CIVIL ENGINEER AND ARCHITECT'S

JOURNAL.

REMARKS ON ARABESQUE DECORATIONS, AND PARTICULARLY THOSE OF THE VATICAN.

(With an Engraving, Plate I.)

Read at the Institute of British Architects, February 3, 1840.

[At a moment when the public attention is so greatly occupied with the revival of decorations in fresco painting, we have much pleasure in being enabled to lay before our readers, on the commencement of a new volume, the following paper, originally produced at the Institute of British Architects. We regret that we cannot devote a larger number of engravings to the illustration of this essay, which must consequently appear somewhat defective in form.]

It is an observation which has been very frequently repeated and very variously expressed, that the proper use to be made of the study of the ancients in their works of art, is not to copy, but to endeavour to think like them. It is admitted to be of little utility to the artist, to imitate the forms of those beautiful models of decoration, which the Greeks and Romans have bequeathed to us, unless at the same time he qualifies himself to apply them judiciously, and modify them successfully, by investigating the principles from which they originate. Among these principles, none is more important, or has exercised a greater influence in bringing ancient art to perfection, than that which has been so well condensed into one line, that

"True art is Nature to advantage dressed."

and if we wish to rival the ancients in the production of what is at once excellent and original, we must, like them, seek the original types in the works of Nature. This was the source from which they drew the various objects which they have modified and combined, not only in their capitals, their friezes, their vases and their furniture, but also in the apparently capricious and fanciful mixtures of different species of animals, and even of foliage and animals, into harmonious compositions, which delight the eye by their graceful and elegant forms, however repugnant to truth, or incompatible with reason. The motives are to be inquired into which influenced the choice of these objects, and the process investigated, by which they fell into the conventional forms in which alone many, perhaps most of them, are now to be found.

That such a course of study would be analogous to the practice by which the ancients themselves attained so high a reach of perfection, we have sufficient proof. Nothing in art can be imagined more conventional than the orders of architecture; and yet Vitruvius endeavours to derive them all from simple principles, and in the Doric order, we can easily trace the original elements of a primitive mode of construction. We shall not so readily perceive the analogy with the female form, given as the origin of the Ionic. It requires a very great stretch of imagination to refer the volutes to the curls of the hair, or the flutes to the folds of the garment. Whatever be the origin of the Corinthian order, the fable which attributes its invention to Callimachus, is as graceful as the order itself; and its repetition by Vitruvius sufficiently indicates it to have been a received principle, that the most conventional forms (and a more conventional form than the Corinthian capital it would be difficult to point out), were supposed to have been originally suggested by the forms and accidents of nature. The least we are authorized to infer from all these instances is, that in the opinion of the only ancient author on architecture to whom we are able to refer, a motive was to be found in every thing the ancients invented, and that in studying the arts it was indispensable to seek and to understand it.

To follow up the subject of these remarks, would open an extensive field of inquiry. They are offered in the present instance merely as prefatory to a few observations on the arabesque style of decoration, illustrated by a short review of the arabesques in the Loggie of the Vatican. It is proposed to inquire how far the artists who designed and executed these arabesques have been indebted to the antique, and how far they have modified the hints derived from that source, so as to adopt their compositions to the purposes they are destined to fulfil. There will also be occasion to notice the derivation of many conventional forms, and the happy adaptation of natural objects by which these arabesques are enriched in a very extraordinary degree.

In speaking of these sort of compositions as arabesques, the term is of course adopted as it is commonly understood, and it is needless to explain that we disregard both its etymology and meaning in applying it to the paintings and stuccoes of antiquity, which represent not only foliage and fruits, but also beasts of every species, and imaginary creatures combined and interlaced together. These decorations have also acquired the name of grotesques, from the grottoes or underground buildings in which they have been found—a term we have perverted still more from the sense in which it was invented.

It is remarkable that the only mention Vitruvius makes of this style of decoration, is in reprobation of it—but he describes it so accurately, that the passage is worth repeating, if for no other reason. After pointing out and classifying, what he considers legitimate objects for painting walls, such as architectural compositions, landscapes, gardens, and sea-pieces—the figures of the gods, and subjects drawn from mythology, and the poems of Homer, he proceeds thus—"I know not by what caprice it is, that the rules of the ancients, (observe, that Vitruvius looks up to the ancients in his day, that is to say to the Greeks,) who took truth for the model of their paintings, are no longer followed. Nothing is now painted upon walls but monsters, instead of true and natural objects. Instead of columns we have slender reeds, which support a complication of flimsy stems and leaves twisted into volutes. Temples are supported on candelabra, whence rises, as from a root, foliage on which figures are seated. In another place, we have demi-figures issuing from flowers, some with human faces, others with the heads of beasts, all things which are not, never have been, nor ever can be. Such is the influence of fashion, that either through indolence or caprice, it renders the world blind to the true principles of art. How can it ever be supposed that reeds can uphold a roof, or candelabra a whole building—that slender plants can support a figure, or their stems, roots, or flowers put forth living beings. Yet no one condemns these extravagancies; on the contrary, they are so much admired, that no one cares whether they be possible or not, so much do mankind render themselves incapable of judging what is really deserving of approbation. For my own part, I hold that painting is to be esteemed only so far as it represents the truth. It is not sufficient that objects be well painted; it is also necessary that the design be consonant to reason, and in no respect offensive to good sense." Pliny also laments that in his time, gaudy colouring and quaint forms were held in greater estimation than the real beauties of art. But with all deference be it spoken, there is another side to the question, which these great authorities seem to have overlooked. Conventional decorations of this kind were within the reach of thousands to whom paintings in the higher branches of art were inaccessible, and a more general diffusion of taste must have been at once the cause and effect of their universal adoption—how universal, the remains of Pompeii reveal to us. If we examine the ancient arabesques independently of these prejudices, we shall find endless beauty, variety and originality; graceful details, combined in consistent and ingenious motives and analogies, and great skill and freedom in the mode of execution. We shall also find reason to doubt whether the introduction of the arabesque style really had the effect of discouraging painting of a higher class, since even at Pompeii, poetical compositions of great merit are frequently combined with the lighter groundwork of the general decoration.

However fanciful and capricious the arabesque style may at first sight appear to be, there can be no doubt that it may be treated according to the general fixed principles of art, and that the artist will be more or less successful as he keeps these principles in view. A due balance of the composition is essential, so that the heavier parts may sustain the lighter through every gradation, and there must be such a disposition as not to cover too much or too little of the ground. Unity of design is to be studied in a connexion of the parts with each other, and in the harmony of the details and accessories, which ought as much as possible to tend to some general aim. It adds very greatly to the value of this species of decoration, when it can be made by these means, significant as well as ornamental. It would lead us much too far to enter upon the subject of colour; but it may just be observed, that in the ancient decorative painting, the balance of colour is strictly attended to. Their walls usually exhibit a gradation of dark panels in the lower part, a breadth of the most brilliant colours in the middle and principal division, and a light ground thinly spread with decoration in the upper part and in the ceiling, an arrangement dictated by the natural effects of light and shade, and reflection. As lightness and grace are the peculiar attributes of arabesque, the foliage which forms its most fertile resource should never be overloaded, its details and modes of ramification ought to be drawn from nature. The poems of Schiller and other German authors have lately been published, with a profusion of arabesque decoration in the margin, which are well worthy of attention, both for the ingenuity with which they are rendered illustrative of the text, and for the accuracy, the *botanical* accuracy, with which some of the foliage and flowers are represented, and which forms one of the greatest charms of these clever and original compositions.

Although the paintings in the Loggie of the Vatican pass under the name of Raffaelle, it is not pretended that they are the work of his hand, nor even his designs. He was indeed the originator and director of the whole, and the character and influence of his taste is visibly stamped in every part. But his coadjutors in the work were artists, whose names are inferior to none in the Roman school but his own, such as Giulio Romano, Perino del Vaga, Benvenuto Tisi, and others, who were occupied not only in the execution but in the invention of the details. Francesco Penni and Andrea da Salerno are particularly noticed as being employed for the figures, Giovanni da Udine for the fruits and flowers, and Polydore Caravaggio for the relievos. It may be worth digressing to mention, that M. Quatremere de Quincy is of opinion, that the sculptures of the Parthenon were produced by similar means, Phidias there performing exactly the same part as Raffaelle in the Vatican—and it is indisputable that the combination of unity of design with variety of detail which characterizes Gothic architecture, could have been produced only by the same system, and by employing the minds as well as the hands, of those by whom the decorations were executed. When we see perfection attained in three distinct styles of art, in three distant ages, by means precisely similar, it is not too much to assume that these means are probably the right ones.

The Loggia of Raffaelle, is an arcade in 13 compartments. The arches are open, or at least, were so originally, toward the court, of which the Loggia forms one side. The opposite side is a wall pierced with windows, one in each arch, giving light to the suite of rooms which contains the great frescos of the prince of painters. The ceiling of each compartment forms a square cove, on the sides of which are the panels containing the series of scriptural paintings, the engravings from which are known as Raffaelle's bible. These are his own designs, and some are known to have been touched with his hand. Both the lateral and cross arches are supported by pilasters about 16 feet high, panelled, and decorated with coloured arabesque on a white ground. Each pilaster on the wall side is flanked by a half pilaster, in which the arabesque is carried through on a smaller scale of composition. It is to these pilasters the present remarks will be confined. We shall find in them as much matter as with the collateral observations to which they will give rise, will fully occupy the time at our disposal this evening.

The description of the pilasters will be taken in the order in which Volpato has engraved them; that is to say, beginning on the side next the wall.[1]

No. 1. Notwithstanding the great variety in the composition and details of these works, we shall find a general unity of design prevailing throughout, with the exception of the last five of the series, which will be particularly noticed in their turn. Whatever form the composition may take, it is rendered subservient to the introduction of four medallions, or tablets, relieved from the back ground in stucco, of contrasted shapes—one like an antique shield—the next circular—the third rectangular, and the fourth in the form known as the *vesica piscis*. These medallions occupy the upper part of the pilaster, to the extent of about one third of the whole panel, while the lower part, to the height of the dado, or somewhat higher, is generally filled in such a manner as to afford a *weight of colour*, sufficient to support itself by the side of that member of the architecture, and the members introduced into its panels, following in this respect the practice of the ancients. These medallions might appear to vio-

[1] We must refer the reader to Volpato's engravings, which were exhibited when this paper was read. They are easy of access.

late the due balance of the arabesques, if they were identified with them; but the composition is rescued from that fault, by the separate character given to the decoration of the medallions, and by their being detached, and hung as it were, independently upon the background. In the general arrangement of the whole, these medallions perform a very important part, connecting the pilasters with the panelled stuccos adjoining, both by their relief, and by means of an accordant style of decoration and a similarity in the subjects represented upon them, neither of which could have been well embodied in the arabesque itself. (see Plate I, Fig. 1.)

It must be admitted, that these compositions considered separately, are somewhat unequal, and the examples to be first passed in review are by no means the best; but instruction may be derived from a consideration of their defects. There are in this pilaster, (No. I,) many graceful details, but the effect is less pleasing and satisfactory than in some others where there is a greater unity of composition, and where the objects are less varied and numerous; moreover, too many of the forms in this example are somewhat stiff. The guillochi which occupies the lower part of the half pilaster, is extremely rich; and we shall find throughout the series, that this part of the composition bears a solid and architectural character, in conformity with the principle which has already been adverted to. Upon the stuccos it is not my intention to dilate; I would merely draw your attention to the beautiful simplicity of the panelling. The antique figures which fill the compartments would require a separate dissertation to describe them only. They harmonize, as before observed, with the subjects contained in the medallions. The clusters of natural fruit and foliage

Fig. 3.

which surround the windows are continued throughout the series of arches, and are greatly varied in detail, though precisely similar in composition. There is nothing conventional in these festoons—the clusters are simply connected together by a string, and are composed of the most familiar objects rendered with perfect truth. (Fig. 3.) The melon, the orange, the chesnut, the tomata, the olive, grapes of different kinds, pomegranates, gourds of every description, pine and cypress cones, are those which most frequently recur, with their foliage and blossoms. The artist has not even disdained the cabbage, the cucumber, and the onion.

No. 2, has the same faults as the first. The frame, with the horse, saddled and bridled, is quite in the spirit of the antique decorations, but it divides the pilaster disagreeably, and is not a proper subject to occupy the principal place in the composition. In the side pilaster we have a rather thin and wiry scroll, of which both the foliage and flowers are conventional, but the convolvulus major twines beautifully and naturally over the fret below.

In No. 3, a closely woven festoon of foliage and flowers is formed into panels—not, I think, very happily, since the arrangement is such as the eye does not very readily comprehend, and even if it were more simple, it would scarcely be applicable, since it divides into many distinct parts the panel which is in itself a single feature of the general design; its integrity is therefore destroyed by this mode of decoration. The subjects which occupy the panels are, however, well worthy of attention. The group of deer, the landscape, the dog chasing a porcupine, the Cupid on the dolphin, and the two winged children manœuvring a dancing bear, are all in the true spirit of the antique. The single figures are less so; an ancient painter would not have placed them on a scrap of earth. In the Pompeian decorations, the detached figures—I do not speak of such as are inclosed in frames, but the *detached* figures—partake of the artificial character of the style to which they are adopted, and if they are not represented as floating in the air, they stand upon a bracket, or a mere line, or on anything but the natural ground. In the panels of the stucco are male and female chimeras, enveloped in a scroll formed of the natural branches of the briar rose.

In No. 4, we arrive at a greater unity in the design, for though it consists of many parts, yet they all bear upon each other, and are mutually connected throughout. The temple which forms the centre of the composition is altogether in the style of architecture which holds so important a place in the arabesques of the baths of Titus and Pompeii. I call it *a style of architecture*, for in the ancient paintings, where it generally forms the framework of the composition, and contributes greatly to that unity of design which distinguishes the ancient arabesque, it assumes a regularity and consistency which fairly entitle it to the appellation of *a style*. The supporting figures are objectionable, for they are in motion—common walking motion. Much more objectionable are the terminal figures which rise from the acroteria of the temple.

My objection to these terminal figures is, that they are improbable. Improbable, I mean, upon certain postulates, which it is necessary to assume before we can reason upon these imaginary compositions at all. The mythology of the ancients has peopled the elements with beings compounded of the human and brute creation, their intelligence being indicated by the first, and their fitness for the region they are supposed to inhabit by the second. There is nothing in ancient art, in which greater taste or judgment is displayed, than in some of these combinations. The animal functions appear in no wise compromised by the mere interchange of corporeal members, between different species. Such combinations, therefore, as long as they involve no glaring disproportions, present nothing repugnant to the mind; and we are so familiarized to them, that we pronounce upon the success of the representation of a triton, a satyr, or a centaur, with as little hesitation as we might upon that of any of the animals of which they are compounded. We are equally ready, or perhaps owing to a stronger association of ideas, *more* ready, to admit of aerial beings, supporting themselves on wings, floating in the ether, or alighting upon a flower without bending the stalk, though these are, in fact, less probable than those born of the ocean or the earth. Between animal and vegetable life there is also a sufficient analogy to attach some probability, or at least to afford an apology, for the graceful combinations between these two kingdoms of nature, invented by the ancients, and adopted to a very great extent in the compositions before us; but, when we come to combine animal life with unorganized matter, the probability ceases; and if, as in the case before us, the unorganized portion is something artificial, and totally out of proportion besides, the combination becomes intolerable. Thus we acquiesce in the metamorphoses of Ovid or the Arabian Nights, as long as certain analogies are observed; but the transformation of the ships of Eneas into sea nymphs, is, as one of our greatest critics has observed, a violation of probability to which nothing can reconcile us.

No conventional form has been more abused than the terminus. Intelligence and immobility are the attributes which the ancients intended it to embody, but their apposite creation is totally different from anomalous compositions like this, into which it has been tortured.

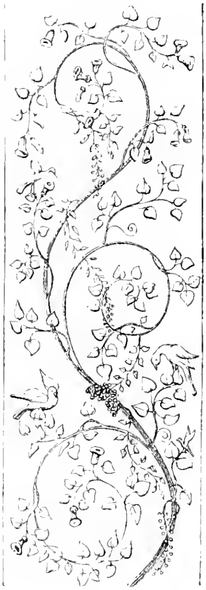
The scroll in the half pilaster of this example is greatly superior to that in No. 2. It is more simple in its composition, and the leaves are broad and natural, and fill the space much more satisfactorily than a multiplicity of wiry lines and flimsy objects, producing confusion, and destructive of breadth of effect.

In No. 5, we arrive at a superior composition; for it must be repeated, we are examining the decoration of a single member of an extensive *whole*, and that however beautiful each may be, unity is a beauty in addition. No object in decoration has been so extensively used as the scroll. The ancients do not appear to have been afflicted with an unhappy craving for novelties, nor to have been haunted with the apprehension that beautiful forms of composition would become less beautiful by repetition. When the most appropriate forms in architecture and decoration were once ascertained, they were continually repeated, but marked with a fresh character, and stamped with originality by those refined and delicate touches which were all-sufficient when they were properly appreciated. We need only refer to the temples of the ancients, to see how pertinaciously they adhered to an established principle, and to the varieties in the proportions of the Doric order, or the character of the Corinthian capital, varieties which we may be assured were neither capricious nor accidental, to see how studiously they availed themselves of all the resources of art in its details. In the same manner with regard to the ever-recurring form of the scroll, as long as the foliage and ramifications of nature are unexhausted, so long will it be capable of assuming an original character in the hands of the skilful artist. A striking illustration of this position may be drawn from the arabesques in the palace of Caprarola, where the pilasters of the Loggie are decorated with scrolls, all similar in composition, but each formed of a different species of natural foliage, without the intermixture of anything conventional, except the regularity of the convolutions. I regret that I can show but three of these beautiful scrolls, and those very slightly represented. They are composed of the olive, (Fig. 4,) the vine, (Fig. 5,) and the convolvulus, (Fig. 6.) The latter being rather thin in proportion to the others, is enriched with birds.

Fig. 4.

Fig. 5.

Fig. 6.



For the magnificent scroll before us we are indebted to the antique. It is an imitation of the well known marble in the Villa Medici, but the artist has made it his own by the skill with which he has adapted it to his purpose both in proportion and colour (see Plate I, Fig. 2.) I would particularly call your attention to the animals, the squirrels, the mice, the lizards, the snake, the grasshopper, and the snail, dispersed about the branches, so well calculated to fill the spaces they occupy, and at the same time producing a variety which would have been wanting, had the foliage only been extended with that object. To the scroll in the half pilaster, it is to be objected, that it is a repetition in small, of that in the principal compartment; but if examined separately, it will be found full of instruction, from the union it displays of natural objects with conventional forms. The spiral line of the antique scroll, is evidently drawn from the natural course of climbing plants. It is conventional in its openness and regularity. The involucra of plants furnish the hint for the base from which the antique scroll is made to spring, and the spathes of the liliaceous tribe for the sheaths, of a conventional repetition of which, the ancient sculptured scrolls principally consist. Thus far for the general elements of the antique scroll, which the artist has implicitly followed in the example before us; but he has enriched his composition without disturbing its unity, by making every sheath produce a different branch, drawn immediately from nature. The birds present an equal variety, and are occupied according to their natural habits, in feeding on the berries and buds, or on the variety of insects which are also introduced. The arabesques in the side panels are to be particularly noticed in this example. A *motivo*, however slight, is always to be desired, and here we see a very graceful one, in the two winged boys, who dip into a vase-like fountain. The winged bear, which occupies the medallion, may be noticed, as a violation of probability. A being to cleave the air, should not be selected from the most heavy and awkward of animals. It is undoubtedly intended for a *jeu d'esprit*, and is quite in the spirit of the antique. The ancient frescos are full of such whimsical combinations, but always, as in the present instance, occupying a subordinate place.

No. 6 is worthy of an attentive examination; the lower part is extremely fanciful, and well adapted to its purpose. For his principal object the artist has chosen the Diana of Ephesus, with her attributes, forming, with some arbitrary decorations, a remarkably well balanced composition, of which the rectilinear shapes contrast in the happiest manner with the flowing lines above. The Diana constitutes a foreground, behind which rises a slender tree. There is nothing more graceful throughout the whole series than the branches of this tree, and the winged boys who sport among them and enjoy the fruit. (Fig. 7.) Equally graceful are those who gather barley from the Cornucopia, and grapes from the loaded trellis above.

Fig. 7.

No. 7 is one of the most remarkable of the series. In this the artist has ventured, and with the most perfect success, to discard every thing conventional, and to represent a natural tree, balancing its irregularities of ramification and foliage by the numerous birds which occupy the branches, where they may be supposed to have been collected by the call of the bird-catcher, who is concealed in the underwood with his bird-call in his mouth. (See Plate I, Fig. I.) One bird, fettered by a limed twig, is about to fall into his hands. It is impossible to admire too much the skill with which this simple *motivo* is worked out. The arabesque of the side pilaster is one of the best of this order; all the parts are graceful in themselves, and well balanced, both in form and colour. This composition is also to be remarked for the introduction of some of the heraldic insignia of the holy see. The keys in saltire, the umbrella, the papal tiara, and the fisherman's ring, with which the successors of St. Peter are invested. I am rather surprised that this sort of allusion has not been more liberally used.

No. 8 is perhaps the least pleasing of the series. There is a total want of unity in the composition, which is merely a repetition of similar designs, and these not a little stiff and formal. There is likewise too great a weight, both of form and colour, toward the top; but the scroll in the half pilaster is beautiful, and closely resembles that in No. 4.

It will be unnecessary to dwell upon No. 9, since it is precisely the same in general character as No. 5, though varied in its details, in the disposition of the animals, and the mode of spreading the lighter ramifications at the top.

No. 10 bears nearly the same relation to No. 4, upon which we have already remarked at some length. It may be further observed in reference to Nos. 4 and 10, that folds of drapery are too broad and heavy to be successful in arabesque, its effect is seldom pleasing. I must also protest against the birds which crown this composition. Nature has provided a variety which makes it quite unnecessary to seek novelty by combining the neck of one species and the tail of another with imaginary wings. The first impression is that these birds are meant for swans; the second, and abiding one, that the artist did not know how to draw a swan—he has not mended them by dressing them in trousers. The scroll in the half pilaster is composed in the same manner as in No. 5, but is better filled.

The next example may be considered a *pendant* to No. 7, which, however, it by no means equals. The stem is a natural reed, each joint conventionally expanded into a calix, from every one of which sprouts a branch of a different species; here are the wild celery, the rose, the blackberry, the arundo, the privet, the grape, the olive, and the barley. The panthers in the stucco panels are appropriately combined with the ivy and grape.

Of the more varied and fanciful compositions on this side of the Loggia, No. 12 is one of the best. It wants unity, and the introduction of so dull a reality as a curtain in the midst of so many objects of pure fancy is displeasing; neither can I reconcile myself to the termini in the upper part. Independently of other objections, they are too essentially terrestrial to enter into combination with these light sprays—an aerial terminus is a contradiction. They are, however, well treated when compared with those in No. 4. The separate parts of this composition are greatly to be admired, especially the *motivo* of the lower part, and the unity which pervades the fanciful combination above it.

No. 13 is in the same style, but much superior. Taking the lower half as complete in itself, nothing can be more gracefully designed, or more perfectly balanced, which latter is, perhaps, after all, the most important point in the composition of arabesques; they will certainly be found more or less pleasing on a first impression, as this condition is more or less perfectly fulfilled. The solidity of the base, the breadth of the parts forming the next step, the lightness of the Pompeian architecture above, and the fluttering character of the objects which surmount it, constitute a gradation which satisfies the eye, while the variety of detail fills the imagination. The upper parts of both these examples abound too much in trivial and wiry details, such as ribbons and strings of jewellery, which are introduced to convey the idea of excessive lightness, but have rather a contrary effect, by producing confusion, and are also too artificial to harmonize with the general character of the composition.

The last on this side repeats No. 3 in the principal composition, and No. 10 in the half pilaster, and therefore requires no observation.

The twelve compositions which occupy the piers on the open side of the Loggia, differ remarkably from the 14 which have been described, and a perfect unity of design distinguishes the majority. This was, perhaps, the more easily accomplished, since (the architecture necessarily differing from that on the side next the wall) the dado is continued across the pilaster, and forms a separate series of panels, each of which is filled with a natural or imaginary being, adapted to the element of water. The half pilasters are also omitted on this side, and a greater breadth of design given to the stuccoes which are brought into immediate contact with the larger arabesque.

In No. 15, the artist has chosen the apparently incongruous subject of fish to combine with his foliage. In a painting by Hogarth we see in the fashionable furniture of one of his scenes, a composition of foliage inhabited by fish instead of birds, and though this absurdity be intended as a caricature of the taste of his day, it is no great exaggeration of the fact. In this design, the foliage and the fish are brought together without the slightest violation of probability; the fish have been hung to the branches; the variety of their forms and colours produce an admirable effect, and above all, they are perfect in the condition, more especially indispensable in objects not intrinsically graceful or pleasing, of being represented with the most absolute truth to nature. We have the haddock, the lobster, the dory, the cuttle-fish, the whelk, the perch, the shrimp, the crab, the gorbill, the muscle, the cockle, the mullet, and the anchovy. This example may teach us that objects for decoration may be sought throughout the whole range of Nature's works with hopes of success.

A more graceful conception than the double scroll which forms the subject of No. 16 it is difficult to imagine. It combines unity of design with an unexceptionable balance of parts, and the most perfect lightness devoid of any thing trivial. This composition might be considered absolutely faultless, were not the two figures placed within the scroll rather too small to bear a proportion to some analogous forms, combined with other parts.

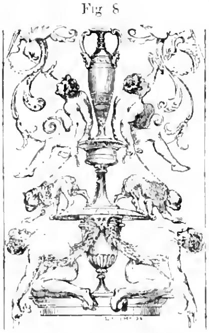
Of No. 17 it can hardly be said the effect is pleasing; but both the *motivo* and the grouping of the musical instruments are greatly to be admired, as well as the skill with which the ends of the ribbon are made to fill up and balance the composition, which is well worthy of study, as showing how advantageously familiar artificial objects may be employed in decoration, when used in their proper place, and not discordantly associated.

Unity is again lost sight of in the design No. 18, but the different objects which compose it, are harmonized upon a totally different principle from any which have been hitherto examined, and the effect is rather dependent upon colour than on form. The panels contrast brilliantly with the white background, and are relieved and rescued from heaviness by the sharp dark lines which surround them; this is quite antique. The component parts of the upper portion of this pilaster must not be passed over unnoticed:—the Cupid and Psyche, the lions with their cubs, the Satyrs grouped with the lower medallion, and the scroll work, which is entirely free from the trivial and confused appendages of which there is reason to complain in some of the former examples.

The general design of No. 19 is the same as in the last example, but its development is scarcely equal, except in the subjects which fill the panels, which are in the highest degree classical and elegant. I ought, perhaps, to have noticed the Tritons, male and female, which occupy the dado of the three last pilasters, but I cannot pass over the bird introduced into this; we are not only presented with the form of the creature, but the skeleton of the fish in its claw indicates its habits also, with the most scrupulous attention to nature; equally true are the bull-rushes in the back grounds.

No. 20 appears to me inferior to any other on this side. The lower part is good, but misapplied, every portion being too minute for its place in the general design. The observation on the drapery need not be repeated. The upper part, besides containing too many trivial and wiry forms, exhibits two or three objectionable matters of detail which it will be proper to point out. The swaddled children are equally unpleasing to the eye and the imagination, and are therefore improper objects for decoration; the heads are also objectionable. To masks there can be no objection—we are familiar with them as a decoration of the ancient theatre; the association does not desert us, though neither the mask nor the manner of its application may have any thing in common with its origin, and though it may be coloured to the life, it is but a mask. But if a bust be introduced, unless it be represented as a sculptured bust, it suggests the idea of mutilation, or what is still more degrading to its character, a coloured wig-block. And even if the heads could be tolerated, nothing can be more ungraceful than holding the festoon in the mouth. Again, in reference to these cornucopiæ (to say nothing of their being ill proportioned and badly drawn), the blossoms and foliage which issue from them are attached at the other end to the scroll above, so that we are in doubt to which member of the composition it belongs, or rather, we see that it confusedly belongs to both. On the sort of termini which finish this arabesque, enough has already been said.

Fig. 8



The remainder of these compositions are of a different character from any that have preceded them, their basis being more architectural, and suited to be the framework of a series of figures which, in the five last examples, reach to a much higher order of art than mere decoration. The lower part of the design No. 21, is in itself beautiful, independently of the figures combined with it, which in composition and drawing, are truly worthy of the Roman school. They do not appear to form any connected subject, like the rest which follow, but the *by-play*, if it may be called so, by which they are united, greatly adds to their value. The attitude of these lower figures, so perfectly adapted to the place they occupy, has its motive in their retreat from the monkies by whom they are threatened, and the monkies are held carelessly by the figures above who are occupied in imitating with looking glasses the dragons, whose undulating forms so gracefully supply the lighter materials of the composition. The medallions which have hitherto accompanied us, are laid aside in this and the remaining pilasters. (Fig. 8.)

Fig. 9.

No. 22 is the first of these connected designs to which I have adverted. In these groups we have the four seasons embodied in personifications truly Raffaelesque:—Spring distinguished as the pairing season—Summer by a group loaded with ripe grain, and the fruits of the season spread at their feet—Autumn by the vintage, represented with a grace and fancy which it is difficult to find words to characterize adequately, (Fig. 9,) and Winter by a composition well calculated as a base for the pyramid which rises from it. To point out the beauties of this painting as regards decoration, is to take a very narrow view of its merits; every one of the 14 figures it contains might be studied as an example of all that is great and graceful in the Roman school of art.

No. 23 also is not more remarkable for the skill with which the parts are combined, than for their separate excellence. The niches and superstructure, supported by caryatic figures, serve as a basis for the three fates drawing the thread of human life. Observe well the pertinency of all the attributes:—the respective ages of the three females, the opening blossoms which surround the first, the ripened fruit which accompanies the second, and the monumental character of the niche in which the third is placed, with the human emblem of mortality at her feet; and to descend to the lower compartment, we have again to admire the perfect attention to nature in the bird, and the berry-bearing plant in which it is feasting.

The next compartment (No. 24), is also full of a moral intention. The principal figures are emblematical of the flight of time. The horary dial supports an admirable group of day and night, with their emblems, dominated by the personifications of the sun and moon; they are accompanied by the well known emblems of time and eternity, and we may find much meaning, even in the steel yard, classically weighted with heads of Janus regarding the past and the future. None of the series is more elegantly terminated than this, though the group does not appear to have any immediate relation to the main subject.

Nothing can be in a higher style of art, than the personifications of Faith, Hope, and Charity in No. 25. To enlarge upon their individual excellence would be foreign to the present purpose. I must only draw your attention to the manner in which they are made subservient to the general design of filling the space they are intended to decorate, and the spire-like form in which they are made to rise from the heavy to the light.

The last compartment is dedicated to the sciences of geography and astronomy. The terrestrial and celestial globes, borne by the genius below, each support figures emblematical of that part of the universe which they represent. On the one lies the earth-born Antæus at the feet of Hercules, who is represented in his appropriate labour of supporting the heavens, while a winged being of celestial aspect crowns the other.

Having now completed the review of this series of arabesques, it is not my intention to detain you by any lengthened observations upon them, such as occurred having been expressed on the immediate occasions on which they arose. I began by stating the principles which I conceived might be illustrated by this review and in conclusion, I venture to suggest the examination and study of arabesque composition as practised by the ancients and the moderns—a comparison of the Baths of Titus, and the remains of Pompeii and Herculaneum, with the Loggia of Raffaelle, the Villa Madama and the Palazzo T, as one of the most instructive lessons that can be devised, upon the varied and original results that may be derived from the same materials, according to the different lights in which they are viewed, the different modes in which they are studied, and the different purposes to which they are applied. In the resources which the decorative artist can call to his aid, the moderns have greatly the advantage over the ancients, since we possess their materials and our own also. For as long as ancient authors are read, and ancient art appreciated, so long will allusion to the manners, customs, poetry, and religion of antiquity be familiar to us, and the symbols to which they gave rise be universally understood; indeed numberless allusions of this kind are constantly before us, and are so familiar that we forget to inquire their origin. In personification, and the embodying of abstract ideas, the field is as open to us as to them, and we see to what advantage it may be turned by the examples we have just passed in review; and if we add to all these objects those derived from the useful arts and sciences which may be turned to account in the hands of the skilful decorator, his resources may be considered boundless. For as we have seen in these examples, it is not the familiar aspect of any object which should banish its representation from works of fancy. Every thing depends upon its proper application. The ancients made the best use of whatever they considered most appropriate, and we must endeavour to do the same. Thus, on the pedestal of the Column in the Place Vendôme, a professed imitation of that of Trajan, modern arms and habiliments occupy the place of those of the Roman period sculptured on the original. Whether this translation be as well executed as it might be, is not now the question. It is noticed merely as being right in principle. One fertile source we have, totally unknown to the ancients, from which materials may be drawn for decoration, carrying with them the invaluable quality of being in all cases significant as well as ornamental—I mean the science of heraldry. I cannot help thinking that the Greeks, who used so much diversity of colour in their architecture, would have availed themselves liberally of the tints of heraldry in their decorations, had they been acquainted with it. From the personal allusions it conveys, it might be made a much more important feature than it even now is, in the decoration of private as well as public buildings, and we have only to study the works of the middle ages for invaluable hints on the mode in which it may be applied. The mere display of shields of arms is but one mode. We shall find heraldry intimately woven into the ornaments of our Gothic buildings, and he who can read its language, may often understand an allusion in what may appear, at first sight, a mere decoration. Thus, one of the mouldings of the tomb of Humphrey, Duke of Glocester, at St. Albans, is filled with an ornament, which, on examination, resolves itself into a cup containing flowers, a device assumed by that Prince, says a MS. in the college of Amis, "as a mark of his love for learning." Heraldry has not been neglected in modern Italian art, and a very well imagined arabesque may be seen at the town hall at Foligno, where the ceiling is covered with foliage spreading from the centre, on the ramifications of which are hung the shields of the nobility of Foligno for many generations. And at Macerata there is a church decorated in a very peculiar style, bearing throughout an allusion to the name of the founder.

A. P.

Pompeii.—The *Frankfort Journal* of the 10th November, states, that the last excavations made in the Street of Pompeii brought to light a number of paintings in fresco, which were affixed as an ornament to four adjoining houses. One of those paintings was remarkable for the extreme correctness of the design, and for the freshness of the colouring. The subject of this painting is Bacchus and a faun pressing grapes, which are borne by a young slave, whilst a child is pouring the wine into a vessel fixed in the earth.

BUILDINGS IN BELGIUM.

By George Godwin, Jun., F.R.S., &c.

"Perhaps no study reveals to us more forcibly the social condition and true feeling of passed generations than that of their monuments."—M. Guizot.

Chapter I.

Belgium contains a multitude of interesting examples of architectural skill in the middle ages, eminently worthy of careful study, and sufficient, from the diversity of the epochs they mark and the character they bear, to illustrate fully a history of the rise and progress of Gothic architecture, and the re-birth of Italian art. An essay on the architecture of Belgium, its peculiarities, its gradual alteration, and its connexion with the architecture of other countries, would be a valuable work, and, so far as I know, is yet to be done, notwithstanding that most of her chief buildings are almost universally known. The present memoranda consist simply of the jottings made during a brief visit to the country in question, and are published with the feeling which has in other cases led the writer to take the same course, namely, that if every one will bring a stone, you may soon raise a pyramid.

The domestic architecture of Belgium offers an infinite variety, and affords numerous hints for present application. Within a very small circle, in some cases even in a single city, examples may be found of the different styles of building which have prevailed at intervals, say of fifty years, from the 11th or 12th century up to the present time. Such towns are a book which those who run may read, and afford a great amount of pleasure and information to those who will pause to think. At Tournay, a most interesting old town, close to the French frontier, towards the western extremity of Belgium, (and of which I shall hereafter speak again,) there are several exceedingly ancient houses; one of an interesting character is situated near the church of St. Brixe. The whole is of stone, and terminates in a gable. The windows, about 5 feet high and 4 feet wide, are each divided into two openings by a small column with plain leafed capital. One of the lower windows has simply a rectangular mullion down the centre, the edges of which are chamfered to within a certain distance from the top and bottom. The string courses, consisting simply of a square member and a hollow, continue through the whole front, and form straight window heads, over which are introduced discharging arches. The adjoining front is precisely similar. In the Rue des Jesuits there are some houses of the same character, but of a somewhat more advanced period. The columns and caps are nearly the same as those before mentioned, and the upper part, perhaps 50 or 60 feet in extent, consists wholly of windows and small piers alternately.

Ghent and Malines display similarly ancient houses.

An early advance upon this arrangement would probably be the introduction of a transom to divide the windows into four, and so to form a *croisée*. In the gable of an old house at Ghent, near the Hotel de Ville, appears a large pointed window, quite ecclesiastical in aspect, with mullions, traceried head, and label. A house near the Grand Place at Tournay affords a very perfect example of the application of pointed architecture to a street front, at the beginning of the 16th century, and the Hotel d'Egmont at Ghent, shows another application of the same style at a period when it was beginning to exhibit symptoms of decline; as also on a much more elaborate scale, does the well known *Maison des Franc Batelers* in the same city.[1]

Near the Eglise de Château at Tournay is a large building, now the Horse Infirmary for the artillery, which would seem to be an example at a later stage of the decline. It is constructed of red brick and stone, and presents gables, pointed headed windows, other square windows divided by mullions, and large dormers in the roof. The mouldings, however, are Italianized, the discharging arches, partly stone and partly brick, which occur even over the pointed headed openings, are made into adornments, and all the ornaments which appear are of mixed design. Later still, the line of the gable became altered into

[1] Mr. Donaldson has made a very interesting series of sketches to illustrate the gradual progression here only hinted at.

a scroll, the mullions of the windows disappeared, and the Gothic panelling on the face of the building gave place to pilasters and entablatures elaborately adorned with figures, fruit, and foliage, as may be seen in numberless examples remaining in most of the towns.[2] The Town Halls and Belfries form a striking feature in Belgium, and in some cases are singularly beautiful. Amongst the privileges granted to the towns when they first acquired communal rights, none seem to have been deemed greater, or were more speedily acted upon, than the right of building a belfry to call together the citizens, and a hall as a general meeting place.

The Hall at Louvain, which has afforded a subject to so many of our artists, is now unquestionably one of the most perfect specimens of a civic building raised by the medieval architects, which remains to us. The whole of it, a pile of crocketted canopies, corbels sculptured into numberless figures, windows, panelling, and elegant turrets, has been restored in a very able manner.

The Town Halls of Bruges, Audenaerde, Ghent, and Brussels, are other examples of great interest. The spire of the latter, which is remarkable for its lightness and elegance, is now being restored, and I cannot avoid making this an opportunity to remark, that the desire to restore the buildings left us by our fathers, which is, at this time, developing itself simultaneously in England, France, Germany and Belgium, is no unimportant sign, and will serve hereafter to characterize the 19th century. Valuable as the result is, the feelings which prompt to it, and of which it is but the evidence, are more important still.

The west front of St. Gudule at Brussels, the cathedral at Antwerp, and St. Bavon at Ghent, are amongst the principal buildings in Belgium, which have been lately repaired. More important perhaps than any, however, are the restorations now going on at the cathedral of Tournay, which is one of the most interesting structures in the country, whether regarded *per se* as a specimen of the architectural skill of two different periods of time, or as recalling by association the events of many ages.

Seen from a distance, with its forest of towers high above the surrounding buildings, its effect is very striking; nor are the pleasant anticipations so raised in any degree lessened by a close approach. In form, it is a Latin cross, with five towers; namely, one on the east, and one on the west side, at each end of the transept, and one at the centre of the cross. The transept is terminated at each end by a semi-circular absis, similar to many churches in Cologne and other parts of Germany. The nave has an aile on each side, separated by piers and small columns bearing semi-circular arches, which in various parts approach the horse-shoe form.[3] Above these, is a second range of piers and arches, of similar or greater height than the first, forming the front of a large gallery, extending the width of the ailes.[4] Over these, is a series of arches against the wall, springing from short piers. The clerestory and the vaulted ceiling were the work of barbarous repairers, in 1777, and took the place of the ancient wooden roof: they will shortly be restored to their original appearance.[5]

All the capitals of the lower columns in the nave are sculptured to represent foliage, and are exceedingly sharp and clear. In earlier times, they were all painted and gilt, and further decorated by scripture mottoes around the abacus. Much of the stone-work is rough and has been covered with stucco: the columns and other parts that were exposed, are of Tournay stone polished.

[2] Lille, a French town, but close to the Belgic frontier, displays a great number of houses of this character, of great richness, and in some cases, much beauty.

[3] The piers occupy a square of six feet on the plan, set diagonally. The openings are 13 feet 6 inches wide, and about 11 feet 6 inches high to the springing of the arch. There are nine such compartments on each side of the nave.

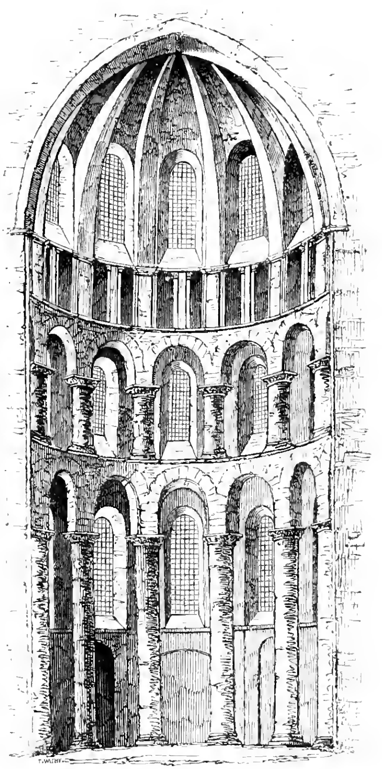
[4] The galleries in ancient churches were used for the purpose of separating the sexes, and even different ages of the same sex. This was perhaps rendered necessary by the custom of *saluting*, which then obtained amongst the "faithful."

[5] During the whole of the 18th century continued injury was done to the building, by injudicious endeavours to support the fabric; many openings, especially in the transept and the clerestory of the choir were bricked up; the capitals of the columns and other decorative portions were covered with whitewash, and the frescoes which adorned the walls destroyed.

The four great arches at the junction of the cross are pointed, and have also been embellished by colour, much of which is still visible.

The interior of the semi-circular absis, terminating the transept at either end, is exceedingly beautiful, and produces a very striking effect. The annexed sketch, (Fig. 1,) may serve to give some general idea of its arrangement. At the bottom, a series of six lofty columns two feet eight inches diameter, and about 24 feet high, built up of ten courses of stone, and placed at a short distance from the wall of the absis, support narrow semi-circular arches raised on legs. Over these are two triforia and a clerestory, and the whole terminates in a half dome with plain ribs converging to a point.[6] The capitals of the columns consist of volutes and of leaves. The base of each pillar has four sculptured leaves at the angles of the pedestal.

Fig. 1.



Originally the choir was about one-third the length of the building, and terminated in an absis similar to those of the transept in form and style. This portion of the building, however, was rebuilt, as is mentioned hereafter, and is now an exceedingly fine specimen of the pointed style, resembling in some respects the choir of Cologne cathedral, although executed much before that wonderful building.

The present choir has an aile and a series of small chapels on both sides, which continue round the east end. Lofty columns bearing acutely pointed arches, separate the ailes from the choir. In each spandril of these arches is a circular ornament in mosaic work, and

[6] These vaults are formed of rubble work, under a wooden roof, and are less than two feet in thickness.

above rise a very elegant triforium and lofty clerestory. Behind the triforium is a series of peculiar quatrefoil lights, blocked up and unknown until lately (as indeed was the whole of the triforium), but now again filled with stained glass.

The choir is elevated above the nave by three steps, for about one-third its extent, and then by a fourth the remainder of the length, and is paved with black and white marble in squares. The high altar has four additional steps. The pillars in the choir were originally constructed with that daring which characterizes many of the earlier efforts of pointed architecture, and soon gave symptoms of insufficiency. They were then strengthened by additional masonry at the back, and even now are remarkable for their lightness and elegance. It may be mentioned, that when the choir was rebuilt, the old chancel arch which was probably semi-circular, was cut away to make room for a pointed arch; as also was the case at the entrance from the transept to the aisle of the choir on each side. Painting and gilding have been used throughout as a means of decoration, and will probably be again resorted to when the whole of the substantial repairs have been executed.[7] A series of flying buttresses (seen in the sketch, at the head of the second chapter), surround the choir externally, and it is between these that the chapels are formed, terminating in gables.[8] The roof of the choir above the vaulting is of oak, and of great height.

Round the outside of the clerestory of the nave there is a continuous gallery, formed within the thickness of the walls, and faced by small octagon columns and arches of the Tournay stone, originally polished.[9] Elsewhere there are various galleries in the walls, so that all parts of the building are practicable.

The same stone is employed in the construction of the building as the rock consists of on which it stands, so that it may be said to be a continuation of the solid substratum. Nevertheless, there are many very serious fissures and settlements, especially in the transept and choir, which need extensive repair. The west front of the building has been disfigured by various alterations; a groined porch in the pointed style extends the whole length of the front, and above it a large pointed window has been introduced, so as to destroy entirely its original character.[10] There is a variety of sculpture under the porch, but the greater part of it is modern and very uninteresting. The cathedral is entered by two doors, one on the north side of the nave, and the other on the south, adjoining the transept. The north door is seen in the external view of the north absis at the head of the next chapter, (Fig. 2,) and is of the transition period. It consists of a semi-circular archway beneath a pointed trefoil arch, the whole profusely adorned with ranges of sculptured figures, animals, and foliage. On each side of the light which occurs between the circular and the pointed arch, is a small twisted column. The four towers of the transept are each different in detail, and have been executed at different times. They all display, however, a mixture of pointed and semi-circular arches.

The whole length of the cathedral within the walls is, as nearly as I can estimate it, 420 feet. The transept, which is nearly in the centre of the building, is 212 feet from north to south. The width of the nave including the ailes, is 70 feet; the choir is a few feet wider. The height of the choir is 110 feet. As a datum for comparison, it may be mentioned, that Salisbury Cathedral, according to Mr. Britton, is 450 feet long within the walls, 78 feet wide in the nave, and that the height of the choir is 81 feet; in other words, it is 30 feet longer, 8 feet wider, and 29 feet lower than that of Tournay.

---

7 In a chapel, south side of choir, the spandrils of an arcade are painted to represent angels bearing scrolls.

8 These flying buttresses are double. The upper arch was apparently formed first, and this being found insufficient the lower arch was then added.

9 There is a curious gallery of this description round the Eglise de Chateau in Tournay.

10 The west front had originally two small towers at the angles. These towers at the extremity of the west front are found in many buildings in Belgium, at the Eglise de Chateau before mentioned, St. Bavon, Ghent, &c.

(To be continued.)

CANDIDUS'S NOTE-BOOK.
FASCICULUS XLIV.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. Were architectural performance to keep pace with architectural promise in this country, we should have some magnificent works; but as ill-luck will have it, either something or other interferes to check the undertaking—to blight it in the bud, or the thing itself turns out wofully inferior to promise—far more liberal than discreet. Of such untoward *turn-outs*, not a few might be enumerated. The poor Edinburgh Parthenon was nipped in the bud: after a few of its columns were put up, it was discovered that "Auld Reekie" was not another Athens, and that an Hellenic Doric face would look as awkwardly upon the Calton Hill, as the helmet of Minerva herself upon an old washerwoman or Meg Dods. It was to have been a temple of Scottish worthies, but some one asked where they were to find worthies to fill it; so though that Parthenon did not fall to the ground—for there was nothing but a few columns to fall, and they are still standing—the scheme did. Not so that of Buckingham Palace; that was erected, and remains a monument of those twins in architectural taste, King George (IV.) and Mister Nash. We were there promised "a magnificent edifice in the most dignified style of Grecian architecture." So magnificent was the original design—so carefully had every part been studied beforehand, that no sooner were the two little boxes intended for wings put up, than it was found out that they were intolerably paltry, and must come down again; and afterwards, another grand discovery was made, namely, that the little dome on the centre of the west-front, was so impertinent as to show itself from the Park, where it was not intended to be seen—and that it would so, might have been ascertained, by a model of the intended structure; but models are expensive things—too expensive to be thought of by such a strict economist, and so careful of John Bull's pocket, as was John Nash! The National Gallery, at any rate its façade, was to have been a prodigiously classical piece of architecture; whereas, its *turn-out* exhibits to us a "beggarly account of empty" niches above, and a cockney display of area railings, and kitchen windows below; to say nothing of a blank pediment—typical, perhaps, of the state of sculpture in this country; of scaffold poles left sticking by way of *garde-fou* between the columns of the portico; of the dome, which looks about as elegant, though somewhat less droll, than the huge cowl at the Old Bailey. The York column was to have rivalled that of Trajan, but as it was found impossible to eke out the Duke's martial achievements so as to cover the shaft with them, that part is left quite bare: nevertheless, it is still, no doubt, the express image of its prototype. The Nelson monument—ah! what was the Nelson monument to have been, or rather, what was it not to have been? There we were told to anticipate a work, of which English art would have reason to be proud. "All the talents" were called out on that occasion, and we have got a tolerably decent model of one of the *five* orders, upon the top of which, Nelson will look like the wick of a candle burnt down to its socket. Again was public expectation raised to the highest pitch: the new Royal Exchange was to be a phœnix—in more senses than one—an edifice worthy of the first country in the world, and of the dignity of the City of London.—Well, if it should not exactly answer to our ideas of what is worthy of the first, it will doubtless amply redeem the promise put forth for it as regards the last, since should it *turn out* to have a more shop-keeping than dignified physiognomy, all the more characteristic may it be of the *dignity* of the City.

II. Hardly will his letter to the *Athenæum* obtain for Professor Cockerell a benediction from Professor Pugin; neither is it likely to be much better relished by Puseyites, Camdenists, and "Ecclesiologists," and whatever other *ists* there may be of the same kind. "Until the subject of our ancient architecture is studied," says the Professor, "the true spirit and intention of that architecture will never be understood; and it will then, possibly, be found, that the intercessions of saints, and the pride of heraldry, are not in accordance with the free spirit of a Protestant, and a free people of the 19th century; and we may then shake off this *dull, unmanly copyism which disgraces our school*, and daring to think for ourselves, *invent* and *perfect* an architecture suited to the ideas religious and moral of our times, and in accordance with the materials and structure of an improved practice!" There's heresy for you, with a vengeance! What say you to that Joseph Gwilt? Why, the smallest of the "small-fry" could have uttered nothing half so mischievous and vile! *Invent*, indeed!—*perfect* too! By the beard of Vitruvius—if he wore one—it is truly scandalous.—"Dull, unmanly copyism!" What say you to that, Sir Robert?—the audaciousness of it must make your hair stand on end. What say you again, Friend Welby, to that same fling at "copyism," and the expressive hint, that the spirit of our ancient architecture is not exactly in accordance with the spirit of the 19th century? Well, after all, you have reason to comfort yourselves that Cockerell did not have a fling at Lord Shrewsbury and his "Inspired Virgins," who turn out, it seems, to be just what might be expected of miracles and miracle-mongers in this 19th century.

III. Architectural painters and draftsmen are privileged, it may be presumed, to lie with impunity, a licence of which some avail themselves so freely, that some of their productions are no better than so many downright graphic falsehoods, which, by greatly exaggerating or flattering the buildings so shown, cause disappointment when we afterwards behold them. It is a very common mode of lying, with them, to draw their figures, which should always serve as a faithful scale to the architecture, so much smaller than they ought to be as to convey the idea of the buildings being very much larger than they really are. Another common piece of deception is to throw in forced effects of light and shade that are never to be seen in the real objects. By no means is it an uncommon trick to put in, not merely positive, but most violent and exaggerated shadows on the upper part of a building, while all below is quite light;—shadows which we must suppose are occasioned by a score of balloons hovering over us just up in the air.

IV. It was to be hoped that the invention of the Daguerréotype would ere this have been turned to a very great account for the study of architecture, and have been made to supply us with perfect and trustworthy representations of buildings, more especially of such as have not yet been represented at all. With regard to subjects of the latter kind, this does not appear even likely to be the case. Certainly it is not so with the "*Excursions Daguerriennes*;" for there some pains seem to have been taken to select some of the stalest subjects possible, and to avoid any which in addition to their intrinsic attractions, would have those of novelty and freshness. This is rather—or more than rather—provoking, so exceedingly perverse, in fact, that one is quite puzzled to account for it. Those who provide the engravings for the large sheet almanacs, seem to have the same relish for staleness of subject. The Cambridge almanac for this year has an interior view of the hall of Trinity College, instead of the façade of the new Assize Courts, as might have been expected, and which, shown upon that scale, would have formed an interesting architectural plate. Again, there has been so very little building going on of late, and that little so undeserving of their notice, that the "Stationers" have been obliged to go to Greenwich Hospital for the subject of the engraving to their almanac. Well, some fifty years hence, perhaps, the turn will come for Cockerell's Sun Fire Office, and Moxhay's Commercial Hall.

V. A sort of materialism seems to be just now prevailing in architectural doctrine, that is more likely to give us able builders and cunning "artisans" than real artists in their profession. No doubt, in a merely utilitarian point of view, it is far more important that we should have the former than the latter. Art may be dispensed with, or treated as something altogether subordinate; but then, let us, in fairness, abate our claims in behalf of architecture itself, as one of the fine arts, and to which, in its quality of such, we look for æsthetic charm and power. "Mere builders," is quite as strong a term of reproach as "mere artists;" and is one by very far more generally applicable than the other, since there are but comparatively few in the profession—and not everyone among the professors themselves—who show themselves to be artists at all; most of them being no better than respectable copyists and plagiarists, unable to catch the spirit of their models, and both preserving *that*, and combining with it some spirit of their own, to give us some fresh ideas worth having, and produce works that might deserve to become models in their turn. It must be admitted that the studies belonging to an architect are very multifarious; yet, while undue stress is laid upon some, which, after all, are but means—the mere scaffolding of his art—that which is assuredly not the least important among them is overlooked, namely, the study of *design*, by which is to be understood something more than that mechanical species of it, which may be learnt *secundum artem*. "But," say the feeble and the timid, "it is safer to stick to mere rules: to pretend to deviate from them, and aim at originality is very presumptuous, and moreover, exceedingly hazardous and dangerous." No doubt: yet it is by that daring which some call rashness, that glory is won, and through perils and hazards that conquest is achieved—in art as well as in arms. Of course those whose valour and prowess are calculated for nothing more arduous and perilous than a sham fight or review, do well to abstain from entering a field where only master-spirits may hope to win, and where even they may fail and fall.

VI. Greatly do I envy Professor Donaldson the possession of that pair of spectacles, which enables him to discern "lines of palaces at Pimlico and on the north side of the New Road," and magnificence in Regent Street! George Robins could hardly have been more liberal of praise in one of his puffing advertisements; and from him such puff would have been received for just what it is worth; but from a Professor and *ex cathedra!* it is *un peu fort*. Such excessive liberality on the part of the Professor at University College, is the more remarkable, because he could not find even one syllable of praise to bestow on a certain building in Gower Street, which some hold to be a very fair piece of architecture, although they are so fastidious in their taste, as to have no admiration for Pimlico palaces—not even for *the* palace, and for Regent Street magnificence. Perhaps the Professor was afraid of alluding or calling the attention of his auditors in any way, to the portico of the building they were assembled in, knowing that its columns had been compared by one very great authority in such matters, to "Ten Cyprians," a class of ladies that ought not to be allowed at Colleges and Universities. As to the great critical authority alluded to—one, by the bye, who holds architectural criticism generally, in abhorrence, much as he has scandalized at "Wilkins' Corinthian Cyprians," he is quite enamoured with those of St. Martin's Church.

NEW ARCHITECTURAL SOCIETY EXTRAORDINARY.

SOME witty but malicious wag has just been amusing himself by circulating a hoaxing *jeu d'esprit*, which imports to be a list of the officers of a new Architectural Society, and in so doing has made exceedingly free with many respectable names, attaching to several of them some of the most ludicrous titles imaginable. We suspect that it comes from some one who is no very great admirer of Mr. Gwilt and his opinions, for that gentleman's name stands very conspicuously at the head of the list, where he is sneeringly designated "Professor of *Latin* architecture,"—a style of architecture never heard of before—and as "Vitruvian Professor," which last title seems to be intended to be a double shot, and to allude contrastingly to Mr. Hosking as the "Anti-Vitruvian Professor," and therefore in Mr. Gwilt's opinion, a Professor of Architectural Heresy and Radicalism. Then we have Mr. Valentine Bartholomew, "Professor of Fruit and Flower-painting,"—an odd sort of appointment in a college of architects; Mr. G. Aitchinson, "Professor of Concreting and Opus Incertum,"—in which last there are, if no professors, plenty of practitioners already. How Mr. Billings will relish the title of "*Itinerant Delineator*," we know not;

but it is a tolerably safe one, since no one will care to rob him of it, the epithet being just next door to that of stroling player. Mr. W. Bartholomew is named as "Honorary Solicitor," and if by that is meant he is to do all the law business of the society "gratis for nothing," he must be a real phœnix in *his* profession—something more wonderful than all other Professors put together. We never heard, before, of "*Baptisterographer*," yet such is the high-sounding title conferred upon a Mr. W. P. Griffith. Besides these, there are a "Custos,"[1] a "Recorder," and a "Cataloguist"! Of Professors of one kind or other there are no fewer than eight; so that the title is likely to become quite a drug—so dog cheap that no one will think it worth having. But the drullest thing of all still remains to be mentioned: would it be believed that these professed and professing "Free-masons" have got a female among them, contrary to the well-known regulations of that mysterious craft? And what office does the lady fill? Is she their "Professor or Professoress of cookery." Oh, no! There would be nothing very ridiculous in that; especially as there is a "Gibbons' *Carver*," and there must, accordingly, be a cook to provide materials for him to operate upon. No, the lady's office is to be that of—guess if you can, but we defy you to do it; therefore not to teaze you any longer, tell you it is to be that of "Embroidress!" Think of Professors, and a Vitruvian Professor among the rest, being jumbled up with an "Embroidress"—alias a Professor of Millinery! O, Vitruvius, how art thou fallen! Dignity of Art, how art thou sunk!—so low that ne'er shall we be able to dig thee out again!

Not contenting himself with this bit of quiz, the author of it has very unceremoniously mentioned several gentlemen as individuals on whom it is proposed to confer Honorary Fellowships, and has even had the audacity to make free with the name of Charles Barry; which is certainly carrying the joke a little too far. He has also put down those of both Willis and Whewell, and we need not say very blunderingly, since the "Vitruvian Professor" holds their writings in such contempt, that he has thought proper to omit them in the list of architectural works inserted in his Encyclopædia. It being merry Christmas time, some license may perhaps be allowed to the jokers and lovers of fun; but we suspect that many of the parties who figure in this *jeu d'esprit*, will consider it very sorry fun—not at all better than a *fort mauvaise plaisanterie*.

RESTORATION OF THE CHURCH OF SAINT MARY, REDCLIFFE, BRISTOL.

[It affords us much pleasure to be able to lay before our readers the following address of the Vicar and Churchwardens of the church of St. Mary, Redcliffe, Bristol, on the proposed works necessary to be done to restore this noble specimen of ecclesiastical building to its pristine grandeur; and we are happy to see that the combined talent of Messrs. Britton and Hosking have been engaged to report upon the necessary works requisite to be done: the one is well known for his antiquarian disquisitions and his love for all that concerns the Christian architecture of Great Britain, and the other for his thorough knowledge of construction and architecture, which insure that the public will have that justice done to the building that it so well merits. We heartily join in the appeal, and do hope that every architect will exert his influence, in stimulating the public to come forward with subscriptions, for the restorations requisite this noble edifice.]

The Vicar, Churchwardens, and Vestry of the Parish of St. Mary, Redcliffe, having resolved upon a public and extended appeal on behalf of the venerable and once splendid fabric entrusted to their care, prepared and circulated, in July last, an address briefly stating the circumstances which appeared to them to justify such appeal. That address explained the preliminary steps which the parish authorities had adopted, and especially their selection of Mr. Britton to advise respecting the decayed state of their church, and the best mode of restoring it to its pristine integrity and beauty, with their reasons for such selection. The result of their communication with that gentleman was his calling to his aid Mr. Hosking, Professor of architecture and of the arts of construction, at King's College, London, whom the Vestry, at Mr. Britton's request, have associated with him in the commission.

These gentlemen having carefully and fully surveyed the church, presented to the parish authorities luminous and detailed reports, on all the matters referred to them, accompanied by plans and drawings illustrative of their views. In the conclusion of their preliminary address the parish authorities stated that the reports were thought too copious for printing on that occasion; but that in a subsequent appeal, an analysis should be given, to embrace their more leading and prominent parts, and illustrated by copies of some of the drawings. It is in fulfilment of this intention, and of the pledge contained in their former paper, that the Vicar, Churchwardens and Vestry, now present this more extended address, in the hope and belief that the public will feel as well satisfied as the parish authorities in their preliminary address stated themselves to be, that the able and eminent architects alluded to, have, in their consideration of the matters referred to them, "been governed by views not less honourable to their reputation for taste and science, than for sound and practical knowledge, and that could the views of those gentlemen be carried out, our city would possess a parochial church, and the west of England a national monument, of unequalled beauty, and one to be visited and admired by multitudes of strangers of our own and of foreign nations."

In their reports on the present state and contemplated repairs and restoration of the church of St. Mary, Redcliffe, Messrs. Britton and Hosking commence by drawing the attention of the parish authorities to the injuries sustained by the fabric, from the long-continued access of damp and moisture, both in the superstructure and foundation walls—produced, as to the *former*, by the insufficient means for carrying off the rain and snow—and, as to the *latter*, by the want of drainage; both which deficiences they principally ascribe to the original arrangement for the discharge of water from the roofs, and want of drainage round the fabric. To the former of these defects, they attribute, in a great degree, the injury to, if not destruction of, the external faces of the Masons' work upon the walls and buttresses. They have, in much detail, set out the nature, extent, and causes of the mischief; and, in a subsequent part of their report, have suggested, with like detail, the extensive and efficient measures recommended for remedying the evils alluded to, and for preventing their future recurrence.

They describe the *roof covering* as, throughout, in a very defective state, though heavy expence is annually incurred in repairing it; and they suggest its entire re-arrangement and re-construction, upon the principles described in their reports.

They have also ascertained and have very accurately described, an original defect existing in the great tower, evinced in a bulging outwards of the external faces of that part of the structure, and produced by an inequality of strength and resisting power between the finely-wrought and closely-jointed masonry of the faces, and the rubble backing which constitutes the main bulk of the walls; and they state that, with the exception of the tower and the flank wall and buttresses of the south aile of the chancel, all the walls and foundations, throughout, appear to be perfectly sound and but little injured. They attribute the settlement outwards of the flank wall first noticed to the want of proper drainage before alluded to, and to the too near approach of graves to the foundations of the wall in question, which are not, in that part of the fabric, more than four or five feet in depth;

[1] Quære, should not this be "Custard-maker?"

PRINTER'S DEVIL.

and they state that, by an attempt formerly made, to prevent the flank from going further, or to hold it up, mischief has been occasioned to the pillars which stand between it and the chancel, and, through those pillars, to the clerestory resting upon them. They express their opinion that the chancel is in an insecure state therefrom, and point out in very strong and clear terms the mischief and danger to be apprehended, unless immediate attention be given thereto; and they enter, at considerable detail, into the comparative inefficiency of the repairs which have been from time to time effected.

Recurring to the tower, they state, that the solid structure of this beautiful work is generally sound and trustworthy, though its *exterior surface has almost wholly perished;* and that from the dilapidated state of the whole exterior and especially of the enrichments previously noticed by them, the tower is unsafe to approach; and they therefore recommend means for excluding persons from passing within reach of the danger to be apprehended from the constant liability of fragments of stone, of no mean size, to become detached, and to fall in every direction.

They represent the masons' work of the spire as generally sound, though the surface of the stone upon the exterior is rapidly disintegrating from the causes described in the report.

In proceeding to advise as to the solid and substantial repair of the fabric, in its more important parts and the restoration of the ornamental parts, Messrs. Britton and Hosking state that so intimate a connexion exists between the parts of such a building as that under consideration as to render what may appear to be merely ornamental in most cases essential to the stability of the structure—that they feel themselves compelled to report on these two heads together: and they furnish very able and sufficient grounds for their determination—but dividing the subject into two parts, viz.:—

First, the tower and spire—and second, the church with the lady chapel, the porches and other accessories.

With respect to the first, it would be injustice to the architects to give in any other language than their own, the suggestions they have offered, viz. :

"*The Tower and Spire.*—This singularly beautiful composition is altogether distinct in style and date from the Church, which has been added to it, and deserves, as it requires, to be considered, not as a merely provincial edifice, and far less as a simple parish steeple, but as a national monument, and in the first rank of the many noble structures of the kind in existence in this country. In magnitude it is exceeded by few; in destined altitude, the larger Cathedrals alone would excel it; and in chaste simplicity of design, combined with elaborately beautiful, but subdued and appropriate, decoration, Redcliffe tower is surpassed by none; whilst it is pre-eminent in its position, on a lofty bank of the Avon, within the commercial capital of the west of England. We have already intimated, that the solid structure of the tower is sound and trustworthy, and that it is capable of being easily made to bear all that it was ever intended to carry. The structural arrangement of the tower itself, and of the existing portion of the spire, give the completest evidence that the original design contemplated as it provided for a spire of the form and proportion exhibited in the accompanying engraving of the church. It would appear, however, that when the church was built the idea of completing the spire was abandoned, as the south-western buttresses of the tower were reduced in projection, and otherwise altered to compose with the west front of the church—and the south-eastern angle was altered, throughout, to extend the nave of the church uninterruptedly to its western front. The tact and skill with which the outer, or south-western angle of the tower was altered, and the fine taste with which the turret pier, in front of the church, which composes with the reduced buttress of the tower, is arranged, to connect the parts of the composition, are most admirable; but not so the arrangement at the other angle—where a low, heavy arch, and an unmeaning blank, upon a heavier pier, obtrude themselves immediately within the church door—contrasting, most disadvantageously too, with the composition of the arches of the aile, and with the clerestory on the other side of the entrance.

"It may be remarked here, that, at the time Redcliffe church was built, the taste which produced the original design of the magnificent superstructure to the tower no longer existed; spires were not built to Gloucester cathedral nor to Bath Abbey church, in the 15th century—as they had been at Salisbury, Norwich, and Litchfield, in the 13th and 14th centuries; comparatively small spires, on lofty towers, as at Louth and Newcastle—or lanterns, as at Boston, indicate the prevailing taste, in that respect, when this church was built, and the abutments of the spire of the original design were altered or removed. In this manner the incomplete or demolished spire was left, and the original composition was shorn of its fair proportions.

"In compliance with the instructions to us, to advise as to such alterations in the restoration of the ornamental parts of the fabric both external and internal as may seem necessary for reinstating it to its ancient and pristine beauty, we urge, most strongly, the necessity of restoring, at the same time, the perished surfaces of the tower, and its immediate accessories, adapting it to receive the completed spire, and carrying on, to completion, that beautiful feature of a masterwork of architectural composition, which, in its truncated state, is but an unpicturesque deformity. Thus the original design may be both restored and completed, and Bristol possess a noble national monument, that will add to the beauty of her locality and to her pre-eminence amongst English cities.

"In restoring the tower, as contradistinguished from the superimposed spire, it will, of course, be proper that the work should be set upright on all its faces; and, in doing this, it will become necessary to take out and reinstate the whole of the ashlaring of the surfaces, even when it might otherwise remain, though that, indeed, is of very small extent. Moreover, all the stones upon which the enrichments occur must, of necessity, be drawn, wherever the enriched surfaces are defective, and these requirements together would involve the reinstatement of all the external surfaces of the tower. Paring old work, and pinning in patches of new stone, where there is not any left to pare, we consider altogether out of the question—as paring would reduce the original proportions of the design—and pinning in, among the pared faces, pieces in the place of stones altogether ruined, would not produce a restoration of the fabric to its ancient and pristine beauty. The absolutely necessary restoration of the faces of the tower, with its buttresses, turrets, pinnacles, niches, canopies, pediments, windows, and their enrichments, parapets, cornices, and corbels, will give the means of doing all that is necessary, with a trifling exception, to fit the tower to receive the spire of its full dimensions. This exception involves an alteration within the church; but we shall be able to show that what is required there can be made, not only consistent with, but most desirable for, the services of the interior.

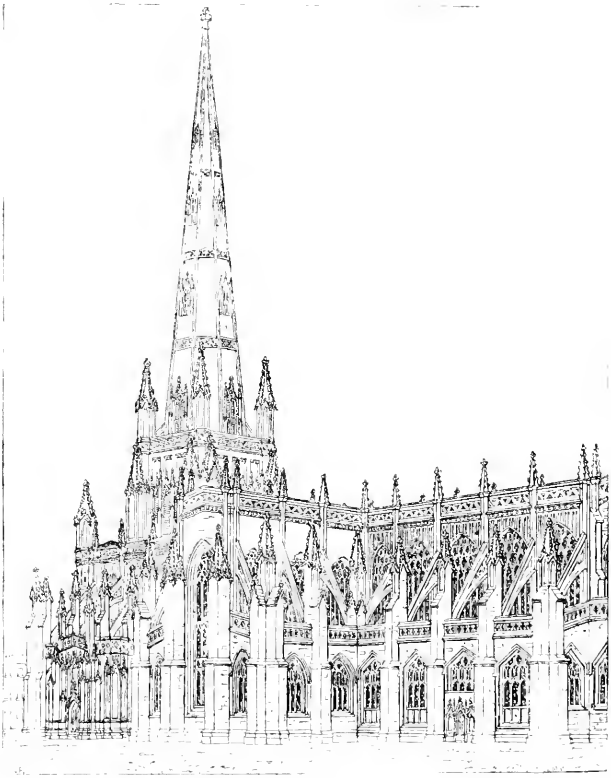
"The existing portion of the spire is, fortunately, quite enough to give the means of developing the original design, whilst it affords demonstrative evidence that a complete spire was contemplated by the original designer of the structure. If lines be drawn from points within the footings of the buttresses of the tower, through the base of the spire, on the summit of the tower, they will follow the sides of the spire, as far as it now exists, and meet at such a height as similar compositions of equal date would justify by analogy. We have drawn such lines, or rather we have set up the present compartment, as it exists, and find that its thrust is within the abutments afforded by the buttresses, and that the sub-structure generally has the strength necessary to carry the superstructure resulting from carrying it up to the height indicated; which height results from a continuation of the same lines upwards, and is further justified by the best existing examples of works of the same class.

"The decorations of the spire, as it exists, are of singular beauty and propriety: the ribs are exquisitely moulded, and the characteristic enrichment of the vertical and pointed mouldings of the tower below, is carried with great good taste and beautiful effect up into the spire, so that nothing has to be imagined in that respect: and we may say with confidence, that the de-

CHURCH OF ST. MARY, REDCLIFFE, BRISTOL.

VIEW FROM THE SOUTH-EAST, WITH THE SPIRE,

AS PROPOSED TO BE RESTORED.



The general style of architecture and the ornamental details of the church above indicated are replete with beauty, and present to the eye of the tasteful and intelligent observer a series of exquisite subjects for study and contemplation as viewed from different points. The view from the south-east, as shown in the annexed woodcut, represents the tall and narrow south transept, with its aisles, windows, highly enriched flying and attached buttresses, perforated parapets, and purfled pinnacles; the south porch, of two stories, and newly designed staircase turret, the flying buttresses and clerestory windows of the nave, with the bold crocketed pinnacle, which surmounts the stairs at the south-west angle; rising above the west end of the northern aisle are seen the upper or belfry story of the noble tower, with its richly adorned panels, boss-enriched mouldings, and perforated parapet; the bold and finely proportioned octagonal pinnacles at the angles of the tower; and rising from among them the lofty graceful spire, crowning and adorning the whole. Of this last splendid and heaven-pointing architectural member of a Christian edifice, there are numerous examples both in England and on the Continent, which are now admired as they deserve to be admired; but, however meritorious and beautiful may be the spires of Strasburg, Salisbury, Freyburg, Lichfield, Norwich, Louth, or others of less note, Redcliffe spire, in form and detail, as indicated by its existing portion,[1] and as it is susceptible of being rendered, with the tower, its legitimate base, may challenge a comparison with them all.

[1] The "existing portion" of the spire is not more than one-fifth of the whole height, or up to the first enriched band.

CHURCH OF ST. MARY, REDCLIFFE, BRISTOL.

VIEW OF THE NAVE, ETC., LOOKING TOWARDS THE EAST, RESTORED.

Divested of pews, seats, and other furniture of a Protestant church, the above print shows the architectural character and details of the INTERIOR of this truly beautiful edifice. If not equal in sculptured decoration to the gorgeous chapels of Henry VII, London, and King's College, Cambridge, it will bear comparison with those justly famed buildings, and will be found to surpass most of the cathedrals and other large churches of our own and of foreign countries in this respect. Although in miniature, this beautiful delineation in wood engraving displays the finely moulded and shafted piers or pillars, with the arches to the aisles, and the panelled walls above them in the situation of the triforium of the large cathedrals. Over this traceried wall is a series of clerestory windows of large dimensions, and of fine forms and proportions, with mullions and tracery. These, it is reasonably inferred, were originally filled with stained glass "casting a dim, religious light" over the whole scene. Connecting, and apparently tying together, the two side walls, is a groin-vaulted ceiling, profusely adorned with intertwining moulded ribs, foliated tracery, and richly sculptured bosses spreading over the whole. In the view presented by the engraving, the eye ranges through a beautiful vista full of the most charming architectural effects. It requires but little stretch of fancy to imagine the exquisite, and indeed sublime, appearance of the whole, were the windows filled with pictured glass, and the ribs, bosses, and capitals of the vaulted ceilings, and of the shafted pillars, with gold and colours "richly dight."

sign, as we present it, of the tower, with the restored spire, is a true presentment of the original intention of the first designer. We may have omitted to state hitherto, however, what is most satisfactory to know, that in the midst of the dilapidation and disintegration which pervade the work, *nothing in the moulded forms or other enrichments, and nothing in the forms and proportions generally, is entirely lost; but specimens remain, from which restorations may be made with certain truth.*

"It will be remarked, that the basement of the tower, in the drawing of the elevation of the west front, shows a greater depth of faced work than appears at present. This we consider it desirable to restore, to prevent the structure from losing any part of its apparent elevation, in raising the level of Redcliffe Street before the north-west entrance to the enclosure; and we have suggested, in the drawings, a re-arrangement of the steps of approach to the church, in accordance with this view. We propose to alter the windows of the tower, from their present forms and proportions, to others, more in character with the design of the superstructure."

For the reasons detailed in the report, Messrs. Britton and Hosking recommend that attention should be *first* directed to the restoration of the *tower and spire;* and that the former should, under the circumstances, not be deferred any longer, if it be desired to preserve this beautiful monument from utter destruction.

Speaking of "the church, with the lady chapel, the porches, and other accessories," after the recommendations before alluded to, as to what are termed the hydraulic arrangements and the proposed reconstruction of the roofs—Messrs. Britton and Hosking suggest a new gateway at the north-west corner of the church enclosure, and other arrangements consequent upon the recent alterations under the Bristol Improvement Act, and for giving more effect thereby to the beautiful edifice under consideration; and, after their valuable suggestions for the substantial repair of the fabric, in the south flank of the chancel and the transept, they refer to their drawings, as showing with sufficient clearness the restorations they propose of the various parts of the exterior of the building; which restorations, they state, are mostly from existing authority within the building itself—and where no specimen exists of the original parts, the restorations are stated to be made, to the best of their judgment, from analogy. Repeating their difficulty of separating the substantial from the ornamental parts they go on to show that many portions commonly considered merely ornamental are either absolutely necessary, or highly useful, to the substantial structure; and after naming several instances of this sort, they add:—

"We do not contemplate, however, and cannot imagine that the necessary and useful reparations are required to be made in merely shaped blocks of stone without the mouldings and other decorations appropriate to them; and, for ourselves, had rather see the church a picturesque ruin, than be instrumental in restoring it to strength without its native beauty. We propose, therefore, *the restoration of all the decorations that ever existed upon the surfaces of the work*, and that with new materials, and not by paring and patching the old."

They add, however, that, in some few cases, the heads of the windows, with the tracery in them, may, perhaps, be preserved.

The architects propose to move the modern attachment to the south porch, also the lobby to the lady chapel, and likewise the sheds and other unsightly objects about the church, and of the doorway and steps at the south-east side of the north porch; they further suggest certain provisions and restorations consequent on such removals.

As TO THE INTERIOR OF THE CHURCH.—The suggestions of Messrs. Britton and Hosking refer to matters of which they describe the restoration for the most part as easy. But the most important restoration of the interior is that at the east end, involving the removal of Hogarth's pictures, and other inappropriate attachments, and the reinstatement of the east and clerestory windows; and they hope to find that reparations only will be wanted to the *screen, between the chancel and the lady chapel.* The latter will want certain alterations, including a new floor.

In the restoration of the spire will be involved some alterations, pointed out by them, at the west end of the church, including a new arrangement for the organ; and they express their hope, that as the whole of the lead and glass must be removed from the windows for the restoration of the mullions and tracery, it may, in the principal ones at least, be reinstated with *stained glass* of an appropriate character.

They also propose in detail numerous and important alterations in the re-arrangement of the *pews and seats*, by which, with an increased seat accommodation, and better command from the pulpit, reading-desk and altar, a more perfect view of the building may be obtained, whilst all the beautiful pillars shall be in every case insulated, that the eye may range over their lofty and symmetrical forms and proportions, from the base to the summit.

The reports of Messrs. Britton and Hosking, with their accompanying drawings, though (for want of more time and labour than they have yet been able to bestow) not made with the fulness of detail required for actual operations, are, nevertheless, the result of admeasurements and of careful delineation of the most important parts; and their observations arise from close examination of the work in general and in detail, upon personal survey and attentive study and consideration of what they have observed; and their *estimates* subjoined are the result of such survey and consideration, and also upon comparison with the cost of other large works of analogous extent and character.

THE TOWER AND SPIRE.—The complete reinstatement and restoration of the tower with its pinnacles, and all its decorations, in the manner, and with the stone they contemplate adopting, will cost about £8,200.

The re-construction and completion of the spire, according to the data afforded by the existing portion thereof, and according to the drawing of the west front restored, and making the requisite additions to the buttresses of the tower, and including the scaffolding and machinery necessary, will cost about £3,600.

THE CHURCH, with the lady chapel, the porches, and other accessories:—

1st.—*The hydraulic arrangements*, including new roofs to the church and lady chapel, the re-arrangement of the north-west approaches, with the earthwork, drains, &c., as recommended in their general report, after giving credit for old materials, will cost £1,850.

2nd.—The substantial repair and reinstatement of the *interiors*, and the repair, reinstatement, and perfect restoration of the whole of the *exteriors* of the church, lady chapel, and porches, including the re-working of the whole of the external decorations in the stone alluded to, together with the alterations and presumed improvements recommended in the general report, it is estimated will cost nearly £21,400.

3rd.—The re-arrangement and refitting of the interior of the church as proposed by Messrs. Britton and Hosking, will cost £2,600. *The whole* presenting a total outlay of £37,650, which, with a due estimate for *contingencies*, in works so extensive, and of such comparatively novel character, cannot, in the judgment of the parish authorities, be safely calculated at a sum much less than £10,000.

It is, however, stated by the architects, that the expense under the 2nd head may admit of reduction, by their finding, on further examination, portions of the work capable of remaining, or of being re-worked and re-applied in places less exposed to the weather, and it is their opinion, that the part of the work contemplated in this section may, after precautions are taken to secure it, generally be distributed over any reasonable number of years.

In allusion to the large sum required for effecting the object in all its proposed details, the parish authorities can but repeat, in the language of their preliminary address, that such an amount is only to be raised by the liberal co-operation of those whom providence has blessed with the ability and the desire to aid in such objects as that for which this appeal is intended: and upon those of our own locality who have been so favoured by providence, they repeat their confidence, that an appeal will not be made in vain for the restoration of a fabric, which, if not wholly the work of a Bristol Merchant, is to be ascribed principally to one of that class. Their confidence is strengthened by the able and energetic support they have received from many and influential quarters, and especially from our local press, by one of whose editors it has been well and eloquently said, that "the question for the public—for the church-going public in particular—to answer, is,—Shall decay be suffered to proceed until restoration shall have become impossible? The amount required (£40,000) for the complete repair of the fabric is certainly great, but when we recollect the large sums which have been raised for the restoration of Hereford Cathedral, and of York Minster, we cannot doubt that the nobility, gentry, and wealthy commoners of Gloucestershire, Somersetshire, and the neighbouring counties will evince equal liberality in worthily upholding—

"The pride of Bristowe and the western land."

The parish authorities, whilst they feel that they cannot, with propriety, divest themselves of the responsibility of carrying out, so far as they shall be enabled to do, the repair and restoration contemplated, feel sensibly that the public, from whom the means of accomplishment is so largely to be drawn, are entitled to every reasonable security for the due appropriation of the sums contributed, and it is therefore the desire of the parish authorities, at an early period after any considerable subscription shall be obtained, to convene a *meeting of the subscribers*, by the majority of whom, subscribing not less than £10 each, six contributors of not less than £50 each shall be chosen, who, with the members of the vestry for the time being, shall form a committee for carrying out such repair and restoration, and for controlling the monies received, and the expenditure thereof.

The parish authorities in aid of the object intended, propose to anticipate, as far as they possibly can be advised to do, the revenues of the estates vested in them for the repair and support of the church, and by means of which, that object has been hitherto (however inadequately) accomplished without the parish having been ever burdened by a *church rate*, and from this source they will apply the sum of £2000, to be paid, as they propose the individual contributions shall be paid, by five equal and successive yearly instalments, to meet the expenditure as it will probably annually progress.

In conclusion, the vicar, churchwardens and vestry, of St. Mary, Redcliffe, venture to quote and apply to their church, the language used by the learned and Very Reverend the Dean of Hereford, in reference to his own cathedral, which at the present moment is in a dangerous state; but which is likely to be preserved and renovated by the united efforts of the benevolent friends of the church and of Archæology.—"Restoration, is the grand object to be achieved, not mending and patching." * * * * * "I earnestly intreat that restoration may be regarded as the one thing sought—sound and legitimate restoration, for which there is sufficient authority."

To the preceding appeal the parish authorities append the following remarks and suggestions by their senior architect, who, as an antiquary and author, has laboured nearly half a century to elucidate and illustrate the ecclesiastical architecture of Great Britain.

M. R. Whish, *Vicar.*
Thos. Proctor, John Farler, } *Churchwardens.*

Extracts from the Remarks and Suggestions by Mr. Britton.

To those persons who are not acquainted with Redcliffe Church, it may be both interesting and useful to give a short account of its peculiarities, beauties, and historic annals.—As a parochial Christian temple it is acknowledged to rank, if not the first, at least in the first class, amongst the many fine sacred edifices of our country. As compared with the cathedral and conventual churches of England, it surpasses most in symmetry of design—in harmony and unity of character—in rich and elaborate adornments—in the picturesque composition of exterior forms and parts—and in the fascinating combination of clustered pillars, mullioned windows, panelled walls, and groin-ribbed ceilings of the interior. I know of no building, to compare with it in all these features, in Great Britain, and I feel assured that there is none superior in graceful design, and beauty of detail, in all civilized Europe. Except the cathedral of Salisbury, which is nearly of one age and design throughout, the other cathedrals, and indeed most of the large parish and conventual churches, consist of heterogenous parts, of varied and discordant dates and styles.

The accompanying views of Redcliffe Church, though on a small scale, cannot fail to impress every eye that can see, and every mind that can appreciate the beauties and merits of architectural design, that the church, now fast approaching ruin, was once, as it may again be made, a splendid edifice; a temple eminently adapted for the soothing and sublime devotions of Christian worship, and also calculated to impress every spectator with wonder, delight, and admiration.

The architect and the antiquary who read plans and sections of buildings, as the musician reads notes, will instantly perceive, that the church referred to is systematically and beautifully arranged; that its interior abounds with clustered pillars, and richly-ornamented ceilings: that its walls are pierced with large windows, divided by mullions, and strengthened with buttresses to resist the thrust of the arched ceilings; that it has a transept of unusual design, being divided into three nearly equal parts; that there is a presbytery, or chancel, with ailes, divided from it by richly-devised screens; that there is a lady-chapel, east of the chancel, separated by another open screen; that there are two small apartments, for a resident chantry-priest, north of the chancel-aile, in one of which is a fire-place, showing it to have been a dwelling, the whole being of unusual occurrence; that there is a double porch on the north flank of the church, manifesting in form, style of walls, ribs, and stairs, different ages of erection; also a porch on the south side, differing, again, from the double north porch in every respect; that the wider and stronger walls at the north-west angle of the plan, show the foundation of a tower; that there is a doorway for entrance at the west-end, central to the nave; and that different flights of steps, from north to south, traverse the west-end, and show that the ground ascends, quickly, in that direction. Aided by the accompanying engravings, of a view of the church from the north-east, and interior; any person may readily understand the architectural characteristics of the church referred to; and those who have studied Christian architecture will immediately perceive its peculiarities of form and arrangement, as well as the chaste profusion of its ornamental details.

Although essential and substantial repairs and restoration be the main objects in the contemplated works, these will be applied to the interior even more than to the exterior of the building; for if the latter may be regarded as the shell, the former is the kernel—if the last be the case, the first is the jewel intended to be preserved. Indeed, as the inside of Redcliffe Church was in its original and finished state an architectural design of pre-eminent richness and beauty—as it was destined by its founder and architect to surpass all its neighbours in originality of composition and elaborate finish, so was it adapted to satisfy the wants and wishes of those for whose devotions it was intended—the present architects, emulous to follow such example, propose to render it fully and completely adapted for the rites, as well as the habits, of its protestant occupants. In doing this, they consider it material to provide accommodation for the many, rather than merely to please the few; they think the clergyman and his congregation should be in such close communion, that the former may be seen, as well as heard by the latter. If the numerous shafted pillars tend to interfere with this communion in some degree, the few sittings, so placed as to be out of view of the minister, will only be resorted to on emergencies. In designing and disposing the altar, the desk, and the pulpit, the organ, and the font, as well as the required number of seats, the most scrupulous attention will be paid by the architects to the ancient usages of the Anglican church, and they confidently anticipate many striking and beautiful scenes and effects when the whole is completed, the subordinate appendages being made to correspond and harmonize with the architectural disposition and character of the church. A learned and travelled clergyman who has devoted some years to the study of the church architecture of the middle ages, writes to me thus—"The harmonious effect of Redcliffe Church must at one time have been quite unrivalled. I am not aware of any cathedral or parish church, either in England or abroad, that contains an equal amount of rich and uniform vaulting. The bosses, more particularly, both in quality and quantity, surpass all that I have met with elsewhere."

To accommodate and afford every degree of comfort to even larger congregations than have generally assembled within the walls of this church, we have made such arrangement of the seats, as shall bring all persons more fully and freely within sight and hearing of the minister; and have also taken especial care to display the complete height and design of all the graceful clustered pillars of the edifice.

There are four palpable varieties of Christian architecture in Redcliffe church, manifesting as many architects, and as many different times when they were respectively designed and erected. The inner north porch, or vestibule—the tower and spire—the outer north porch—the body of the church, with the lady chapel, and the south porch—we feel assured were built successively, and it is generally admitted, that an older church was removed to give place to the present nave and chancel with their ailes and the transept. The oldest of these members, *i. e.* the vestibule, is of a date between A.D. 1200 and 1230. "In 1207 Lord Robert de Berkeley granted to Redcliffe church, at the request of William, the chaplain, his fountain of water from Huge well, for the friars of St. John the Baptist in Redcliffe." Lands were conferred on the same church, about that time, plainly showing that there was one then in the parish. The tower and spire we may safely refer to the reign of Edward I, as corresponding with known specimens of that age. According to the chronicles of Bristol, Simon de Burton, who was mayor in 1293, "began to build the church of St. Mary de Redcliffe, when John Lamyngton was chaplain,"—(Evans's "Chronological Outline.") Seyer, in his "Memoirs of Bristol" (Vol. II., p. 77) from MS. Calendar, more cautious and particular, says, "It was about the year 1293 or 1294 that Simon de Bourton, a person of wealth and consequence, who was Mayor of Bristol in that year, and bore the same office six times, built the church of St. Mary, Radcliffe, where the eastern end now is." Here we find it positively stated by one writer, that the church was built, and by another that it was begun, at the above date. To us it is quite clear that no part of the present church is so early as 1294.

YORKSHIRE ARCHITECTURAL SOCIETY.

Sir—My attention has been drawn to a letter in the last number of your *Journal*, containing remarks on the Yorkshire Architectural Society. What is *personal* in the letter may be safely left unanswered, as the tone in which it is written will be its best counter-agent.

With respect to the Society, your anonymous correspondent has made several statements, of the falseness of which I hope he was ignorant; these appear to require some notice.

In his letter, it is said "The prospectus contains the names of two architects only, and neither of them attended the Autumn meeting."

Before the Autumn meeting, the prospectus contained the names of *twelve* architects; I saw four present at the meeting, and I believe more attended.

Your correspondent says, "*Two meetings* are to be held in the year, and from the information given at the last, it appears, that for general accommodation, they are to be in the remote corners of the country."

Two *general public* meetings will be held during the year, the places of meeting being *various*, and appointed by the Committee, so as to suit the convenience of the members generally.

Again, "All admitted must be members of the Established High Anglo-Catholic Church." It is true that this Society for promoting the study of *Ecclesiastical* architecture, admits only churchmen; but without respect to their peculiar sentiments. No exclusion of any member of the church has yet taken place, and the Society, amongst its 400 members, includes many churchmen of different opinions.

The last misstatement is, that "the standard for all buildings is to be Parker's Glossary."

At the request of a dignitary of the church, a list of elementary works on Gothic architecture was added at the end of the report, as a guide to any member beginning the study of architecture; in this list Mr. Parker's Glossary was mentioned, together with the works of Rickman, Bloxam, &c. This so far as I know, is the only foundation for the imaginative writer's assertion, "that the standard for all buildings is to be Parker's Glossary." Whether the insertion of such venturous statements on the authority of an anonymous writer suits the character of a respectable periodical, I leave to your judgment.

I am obliged by your having pointed out in your Editorial remarks an unintentional omission in the advertisement there alluded to. It was considered, or rather assumed without consideration, so much a matter of course, that the architect whose plan should be chosen, would have the carrying out of his design, that no express mention of this was thought necessary.

I am, Sir,

Your obedient Servant,

S. Wilkinson,

Hon. Sec. to the Yorkshire Architectural Society.

Leeds, Dec. 5th, 1842.

THE KENTISH TOWN COMPETITION.

Sir—Should what I am about to say appear too pointed against a particular party, that individual has mainly to thank himself for the pointedness of some of my remarks. When we find a man pursuing that very course which he has both loudly and publicly reprobated in others, and protested against—we must suppose, upon principle—when we see a would-be Cato all at once changed into a Clodius, such an offender has little reason to look for that lenity which might perhaps be extended to those, who, whatever their conduct may be, at least make no parade of being greatly more upright and conscientious than their neighbours.

That after expressing himself decidedly hostile to competition, after actually saying, "I have endeavoured to go into the *strongest possible condemnation* of which I am capable, of the depreciating effect of competition in architectural design;" that after thus pledging himself in print, and the strongest possible manner, to be opposed to the system of competition in any shape, Mr. Bartholemew should have become, or have even thought of becoming a competitor for the intended church at Kentish Town, is indeed most strange. He cannot disavow those words, and a great many others to the same effect, unless he should now choose to say, that although his name appears upon the titlepage, he is not the *bona-fide* author of the work; and did not even know until after its publication, what opinions it really contained; yet hardly will he resort to such evasion. He must therefore put up with the mortification of having been so imprudent as to publish a good many very harsh reflections that now recoil upon himself. Hardly is it possible to conceive how a man who has denounced the whole system of competition in the most unmeasured—even virulent terms, as one compounded of folly and knavery, and which he accordingly laboured earnestly to put down, should now abet it; should not only join in a public competition, but in doing so, should unfairly evade the restrictions laid upon others, having good reason to know that his doing so would be winked at.

In the list of printed conditions, one was to the effect that none of the drawings sent in should be *coloured*, but merely tinted in sepia. This was sufficiently explicit; there was no possibility of mistaking it. Nevertheless, Mr. Bartholomew's principal elevation was a coloured drawing; and so far he violated the instructions which his rivals had been obliged to conform to: consequently he ought in justice to have been put *hors de combat* at ence. The best that can be said in excuse for him in that matter, is h so far he practised no deception, for the most ignorant set of men must have been able to see whether a drawing was coloured or not, and if they choose to violate the pledge implied in their own instructions to the competitors, the dishonesty rests with them. At any rate *they* have no cause to upbraid Mr. Bartholomew with having acted unfairly. But there was one little *licence* of another kind taken by Mr. Bartholomew, by which they were probably imposed upon. I here allude to the singular discrepancy between the geometrical elevations and the perspective view, in which last, several alterations were made, in order to *improve* the effect. Improvement there was, but it was also direct *falsification.* It was tantamount to saying, "execute the building from this set of designs, and such will be its appearance." And if that does not amount to one of the *tricks* practised in competition, I know not what does. By no means do I pretend to say that Mr. Bartholomew is indebted for the decision in his favour, mainly to that artifice. He would probably have been equally successful, had he taken the liberty of evading the condition which required perspective drawings. I merely mean to say that such artifice was actually practised; and by whom? —by no other than the immaculate and conscientious Mr. Bartholomew, the violent and ultra anti-competitionist, who, in another edition of his book—should it ever reach one—may now bring forward some examples of the manœuvres practised in the competition for the Kentish Town Church.

Without any additions, however, there is enough and more than enough in his book at present, to convict the author of the "Specifications" of the most flagrant inconsistency. Or are we to suppose that he purposely left himself a loophole to creep out of, in the remark, that "what every respectable architect who has any real professional business to attend to, thinks of competition, may be gathered from the well-known fact, that none such is found to send in a competition design, unless he possess, or fancy that he possess, *direct influence for obtaining the prize!*" After this, we are compelled to suppose that Mr. Bartholomew would not have entered into the competition in question at all, had he not good reason to imagine beforehand that the prize would be secured to him by influence behind the curtain. It seems, therefore, after all, that violent as he is against competitions in general, he has no objection whatever to enter into one, provided he knows that it is a mere mockery as far as others are concerned, and that however superior may be the merit of other designs, the preference will be awarded to his own! He has now put beyond all doubt that he had but one inducement, and that founded upon what is most corrupt in the whole system of competition; upon that which really brings it into disgrace, and renders it nothing better than a system of dishonesty and intriguing—where one is to be favoured, and all the rest are to be duped—being invited to throw away their time in making drawings for what is arranged and all but finally settled beforehand. In the Kentish Town affair, however, there is something to console those who have been duped and disappointed; for not only is it a consolation, but even a triumph to find that Mr. Bartholomew's anti-competition rigour has thawed and melted away—probably owing to the late very hot summer; and that he has to all intents and purposes publicly recanted the furious invectives he has uttered against competition in his book. Therefore, those last now stand for nothing—except as so many proofs of his singular sincerity and consistency.

I remain, &c.,

NOT A. B. BUT B DUPED.

THE INVENTOR OF THE DREDGING MACHINE.

SIR—I observe, with some surprise, from a review in your Journal of last month, that you still consider the claim of the inventor of dredging by steam power to be amongst the number of those which are not yet satisfactorily established. You refer to a paper in the *Civil Engineer and Architect's Journal*, for January, 1839, wherein the invention is unreservedly ascribed to my grandfather, John Hughes, and during the four years which have elapsed since the publication of that paper, no syllable has ever been advanced in opposition to this claim—a fact which carries with it peculiar weight to the minds of those who, like myself, are fully aware of the very large circulation which your Journal commands. An individual, however, has at last thought proper to assert—I am willing to believe without the sanction of Messrs. Rennie—that the dredging machine is the invention of the late Mr. Rennie, their father, who first used it at the Hull Docks. In commenting upon this assertion, you observe truly, that a very important fact is not mentioned, namely, the year in which Mr. Rennie first introduced it at the Hull Docks. I shall, therefore, supply this omission in order that you, Sir, and the readers of the Journal, may estimate the value of the assertion thus rashly hazarded by a self-constituted champion of Mr. Rennie. It will be found that the first steam dredging engine employed at Hull was that used for cleansing out the Humber Dock, which was not opened till the 30th of June, 1809; and the following passage from Mr. Timperley's account of this dock will fix the time at which the engine was first used.

"This dock was not cleansed for three years and a half after it was opened, *the dredging machine and mud boats not being completed until then.*"[1] Hence it appears that the dredging machine could not have been employed at Hull before the end of 1812 or the beginning of 1813.

While this is the fact with respect to Mr. Rennie's claim, I am in possession of a report by my grandfather, dated in 1820, where he describes minutely every particular of his invention of the engine, and first employment of her at Woolwich, as far back as the year 1804; and not until it can be shown that the engine was invented before this last date will the claim of my ancestor be at all invalidated. I believe that Messrs. Rennie have far too high a respect for honour and truth to dispute for one moment a fact with which their respected father must have been so perfectly well acquainted, as that of the invention of the machine, and her first employment by my grandfather at Woolwich, in the year 1804. At the same time, it is possible that a person less intimately acquainted than they must be with the history of an invention of this nature, might be misled by the fact that dredging machines, on the old bag and spoon principle, were employed at Hull 50 or 60 years ago. It is even admitted, that a bucket engine worked by horses, was used at Hull from about the year 1782. This engine was probably the work of Mr. Rennie. That it bore no resemblance however to the modern steam dredging engine is abundantly proved by the fact, that many years after the horse machine was erected at Hull, the application of steam power to the dredging engine was unsuccessfully attempted by Trevethick and many other able engineers. Had Mr. Rennie's machine of 1782, been anything like the steam dredging engine, the simple application of steam could scarcely have baffled the exertions of so great a man as Richard Trevethick, with others of his contemporaries.

With respect to your observation "that the late Mr. Rennie, together with his talented sons, have brought the machine to that great perfection it has now attained," I would simply remark, that the engine built by Messrs. Donkin for William Hughes of Inverness, and used by him on the Caledonian Canal, was the most perfect ever constructed. See accounts of this engine in Baron Dupin's work on the resources of Great Britain, in your *Journal* for January 1839, and in a paper read before the Institution of Civil Engineers during the last session.

I am, Sir,
Your obedient servant,

8, *Duke Street, Westminster,*
December 15th, 1842.

SAMUEL HUGHES.

AMERICAN MARINE STEAM ENGINES.

SIR—A late number of your *Journal* contained some remarks concerning American Marine Steam Engines, which were in a spirit very unlike the usual tone of the English press in descanting upon "Brother Jonathan's" available genius in such matters. Candid, fair, impartial criticism, no matter how close it may chance to "cut," will do much towards removing those mutual prejudices which unhappily exist to such an extent, that the mere imprint of "American" or "English," is oftentimes of itself sufficient to place the merits of any work without the pale of respectful controversy.

This should not be; there is not the least of necessity or of policy in being thus deprived of the benefits of each other's experience; as advantages in some shape or other, most undoubtedly belong to each, and only require to be known in order to be secured. As an illustration, might be adduced the acquaintance already formed through the establishment of your Trans-atlantic Steam Navigation Companies. One or two instances will suffice. In the English marine engine we see a connecting rod 15 feet long, and $10\frac{1}{2}$ inches diameter, subjected to the same direct stress with the connecting rod of the American engine, and which is 24 feet long and 6 inches diameter; two thirds *less in area*, and one third *greater in length*, and yet performing equally well the same labour! By this, we are taught, that

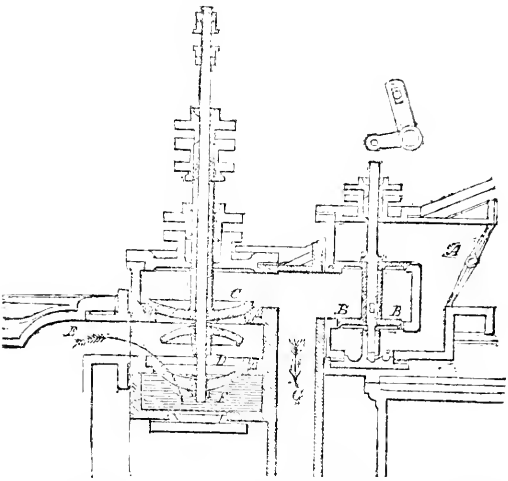
[1] See Mr. Timperley's account of the Harbour and Docks at Kingston-upon-Hull. Transactions of the Institution of Civil Engineers, vol. 1, p. 22.

while the English engines are certainly at *one extreme*, we are probably at the other. Again; the *Great Western*, if you please, comes over here with decks as "clean" as a "man of war." and returns with the singular notion, that on her quarter deck, can be erected, at a trifling expense, a saloon equal in every respect—and superior in many—to the one below, and making an addition to her accommodations equal to one third of all her cabin room below deck!

Notwithstanding the unequalled degree of perfection to which steam navigation upon our rivers has attained—excepting, of course, the great river of the west—the impression is very prevalent abroad, that in the attempt to compete with the "Lion of the seas," we shall be found wanting—an impression unfortunately, most consistent with a certain illegitimate specimen of "Yankee enterprise," which has recently visited your shores. We think, however, that the time is not far distant when, with a ship exceeding in length the ordinary proportion, with engines having greater length of stroke so as to admit of working steam at a greater pressure without adding weight to the working parts, with paddle wheels large in diameter, very narrow, and making revolutions not less than 20 per minute; and with boilers adapted to a pressure of 15lb. to 20lb., we shall be able somewhat to "shorten the distance" which separates us from the "land of our fathers." Certain it is, that our ship-builders and engineers will not be satisfied with a steamer which will require, for a passage to Liverpool, more than *ten days* of good weather.

You were pleased to notice in a favourable manner the engines of the Spanish steamers *Regent* and *Congress*, built by the late firm of Ward, Stillman and Co., of the Novelty iron works, New York, and to intimate a wish to have the details of their arrangement. In answer to which, I take pleasure in sending to you a detailed account of those vessels, together with so much of a drawing of their engines, as will answer the purpose of your inquiry, and which I am authorized to do by Messrs. Stillman and Co.

View of the Upper Valves.



A, Throttle valve. B, Expansion valve. C, Steam valve. D, Exhaust valve. E, Upper part of cylinder. F, Exhaust pipe. G, Steam pipe to lower valve.

Vessels:—	Feet.	Inches.
Length on deck	154	0
Breadth	30	8
Ditto at water line	28	8
Depth of hold	14	6
Draft of water	8	6
Burthen	671 tons.	

Frame of white oak, live oak, locust and cedar. The floor of white oak, laid close and caulked inside and out. Planked with white oak; fastened throughout with copper thorough bolts, composition spikes and locust treenails.

Engines:—
Diameter of cylinders $42\frac{1}{4}$ inches.
Length of stroke 4 feet 7 inches.
Diameter of paddle wheels 18 feet.
Length of board 7 feet 6 inches, and width 2 feet 6 inches.
Pressure of steam 10lb.
Number of revolutions per minute 26.
Total weight of engines, wheels and boilers 100 tons.
Two copper boilers 22 tons.
Length of boilers 14 feet, height 9 feet, and breadth 8 feet.
Total of fire surface 1400 feet.
Speed of vessels 10 miles per hour.
Cost of vessel, engines and boilers, about 150,000 dollars.

It would be trifling, I fear, with the patience of your readers, to enter into a detailed description of the drawings, representing, as they do—with one or two exceptions—but an "old acquaintance," the "side lever engine;" the principal deviation from which, is the steam valves, and perhaps the air-pump bucket. The valves are shown in the section in the same position as in the drawings you refer to as having received, and which has recently been published in the London *Mechanics' Magazine*. As to the merit of this arrangement of the valves, I will not now offer an opinion, except that they are not generally used here for large engines.

As English engineers—either from strict fidelity to the *opinions of Watt*, or from much actual *experience*—have held us guilty of divers "barbarisms," in our substitutions for the use of the "slide valve," I shall make this matter the subject of another communication, accompanied with a sketch of the most approved form of the "double" or "balance valve."

The bucket of the air-pump, as shown in the separate sketch, for aught I know, may not be peculiar to this country, nor is it universally adopted here; it has been found, however—in situations where the condensing water is free from sand—to be far more efficient and durable than any other in use.

The "bilge injection," shown near the bottom of the condenser, is here thought to be an essential part of the engine of every steam vessel. And instances have occurred in which the use of it has been attended with the saving of much life and property.

With your permission, I will from time to time furnish your readers with notices—accompanied with drawings—of such improvements in American engineering. as may be thought interesting, or of such of its features as are not familiar to our transatlantic brethren generally.

I am, Sir, &c.,

New York, July 1842. F. W. S.

In our Journal for June last, we noticed that the Spanish government had ordered, and obtained from New York two war steamers, named the "Regent" and "Congress," and in commenting thereon we observed, we wished some further information before we gave any opinion on the subject; we were favoured with a lithographed external view of the engines, but we desired to look below the surface. Our wish has now been complied with, we are in possession of an apparently perfect section of the engines of the *Regent* and *Congress* steam ships, together with F. W. S.'s remarks thereon, and which we now publish. We thank him, and think, if his intentions are supported by engineers of the Old and New World; it will do much towards the explosion of prejudice, the extension of knowledge, and general good of mankind; that we heartily co-operate in this view, we plainly avow, as in fact our remarks in our last December number fully prove. We are, therefore, surprised at the opening paragraph of our correspondent, and we are unconscious of having admitted any thing into our columns which could offend his taste. If we have descanted upon "Brother Jonathan," it was more in playfulness than anger, not as an opposing race, but as descendants of one common stock, to which *genius* is common. We think, however, our correspondent's reprehensions are misapplied, as we do not recollect using the phrase *he* complains of. With this exordium we at once proceed to an analysis and consideration of the engines of the *Regent* and *Congress*.

The engines are of the *beam* kind, and scarcely to be distinguished from those of the *Megæra* by Seaward, published by Weale in his Tredgold, pl. 49, vol. 2. The *architecture* is very similar to the engines of the *Tiger*, by Edward Bury. (See Tredgold, vol. 2, plates 110 and 110 a.) In one point they differ, in the use of circular valves instead of the D or Murdock slide, and in this it resembles another emanation of American intellect, called the *Royal William* (now *Isabella II.*) which made the voyage to England in 1832, and subsequently figured in the Spanish war.

The cylinders are $42\frac{1}{2}$ inches diameter and 4 ft. 7 in. stroke; at 26 strokes or 238 feet the power is equal to $71\frac{1}{2}$ horses each, or 143 horses collectively. This is nominal power as calculated by the rules of the late Mr. Watt, applicable to steam of $2\frac{1}{2}$ or 3 lb. per inch, but in this case we have a pressure on the safety valve of 10 lb. per square inch, so that the *actual* power will probably be 150 per cent. above this, depending entirely upon the expansion used, and we may further observe, that with a suitable arrangement, circular valves may be made to produce any degree of expansion, at pleasure. The air pump is 22 inches diameter, and about 2 ft. 6 in. stroke, = a content of 6·6 cubic feet. Cylinder $42\frac{1}{2}$ in. × 4 ft. 7 in. long = 49·46 feet content, which divided by 6·6, makes the cylinder 7·5 times larger than the pump, just the usual proportions of English engines. The condenser is 2 ft. 5 in. fore and aft, 3 ft. 5 in. in width, and 4 ft. high, with proper deductions is equal to a content of 24 cubic feet, and 71·5 ÷ 24 = nearly 3 cubic feet per H.P. The circular steam valves are $11\frac{1}{2}$ in. diameter = 103·86 area, the eduction valves are 10 in. diameter = 78·54 area, or rather more than a square inch per horse, a very ample allowance, and much exceeding Mr. Watt's rules, as will be seen by reference to Farey and other works, but taking into consideration the increased density of the steam employed, is judicious, and about on a par with modern *slide* valve practice. Our correspondent is wrong in supposing that English engineers have adhered to the slide valve "from strict fidelity to the opinions of Watt." It is otherwise; they have departed therefrom and followed Murdock, his disciple, who patented the D, triangular, or other shaped sliding valve, in his specification of 1790. (See Farey, p. 677.) We are at a loss, also, to find any novelty in the construction of the circular valves; they appear to us precisely similar to those used by Mr. Watt[1] in his engines of 1808. He used circular pipes, and here we have rectangular passages. (See Farey, plate 20.) We are equally obtuse respecting the air pump, of which we have an isometrical drawing, and can find nothing new therein; if our correspondent alludes to the packing ring similar to that of the piston, we may say that system has been followed in this country since the year 1826, perhaps earlier. The bilge injection is in the same category.

There is merit in the adaptation of a double beat expansion valve, though it is by no means new, and we think we can suggest an improvement, as the lower face can never be tight (see the annexed engraving). The other parts of these engines are so much like the best English practice, that it is needless to pursue the inquiry farther. The space occupied in the vessel for each engine is 16 ft. fore and aft, and about 5 ft. 9 in. over the main beams.

On the whole, we think the engines of the *Regent* and *Congress* to be highly creditable to Messrs. Ward, Stillman & Co., of New York, by whom they were manufactured, not only as evincing considerable judgment in detail, but more so, in their selection of the common beam engine, which, after all, appears to be the best kind yet produced.

[1] Or rather his successors, Boulton and Watt. Mr. Watt retired from business in 1800.

THE NEW HOUSES OF PARLIAMENT.

The fifth contract for erecting this national and truly magnificent work has just been entered into, and Messrs. Grissell and Peto are again the successful competitors. This contract or portion of the work is by far the most important that has yet taken place, embracing as it does the Victoria Tower, the Royal Gallery, the Houses of Lords and Commons, with other important and necessary adjuncts thereto. The following particulars have been obtained:—

The Victoria Tower, or Royal entrance, necessarily occupies the first position in the arrangement, whether as regards the order of description or the magnitude of its structure, which perhaps will be one of the richest and most gigantic specimens of Gothic architecture that this or any other country can boast. Beneath this tower the Royal entrance will be formed, presenting an area of 60 feet square, into which the Royal and other state carriages will be enabled to drive with the most perfect ease, turn round at the foot of the Royal staircase, and depart at the entrance on the south side. The upper stories of the tower will be used as secure depositories for public records and state documents. The external square of the tower will be 78 feet at the principal floor level, from which point it will be ornamented with the richest specimens of Gothic sculpture to the height of 240 feet, reaching to the base of the four crowned turrets by which it will be surmounted. The entire height, from the bottom of the tower to the top of the turrets, will be 300 feet.

The Royal entrance-hall or vestibule is the next object of interest included in the present contract, and will be approached from the right-hand side of the tower, leading from the principal staircase to the Royal Gallery.

For the Royal Gallery, the next in order, no pains have been spared on the design to render this portion of the edifice of surpassing richness and magnitude. The upper part of the walls will be of the most elaborately-sculptured designs of Gothic ornaments, while the lower portion of the walls is divided into compartments intended for the reception of the most exquisite subjects in fresco painting.

The Royal Robing-room will be next approached from the Royal Gallery, and will strictly harmonize with the fittings and ornaments of the latter. It will be a most splendid apartment, 40 feet in length and 30 feet in width, immediately adjoining the house of Lords, with entrances for the Sovereign on each side of the throne.

The Bishops' Robing-room, a large apartment on the right-hand side of the Robing-room of Her Majesty, will be appropriated to the use of the spiritual peers.

The House of Lords comes next in the order of arrangement, and will be situate on the principal story, preserving a level throughout with the old floor of St. Stephen's Chapel, so that the entrance for the peers may either be obtained along the corridors from the river front, or by that leading from Old Palace-yard. The size of the House of Lords, as well as that of the House of Commons, will be reduced to the smallest possible limits compatible with the required accommodation, and to give them that form and arrangement which will afford the greatest number of sittings in the smallest space, bring the members nearest to each other and to the speaker, and be the most convenient for carrying on the ordinary routine of business.

The two houses will be placed as nearly as possible in the centre of the whole mass of buildings, this being considered the position best adapted for communication with each other, and with their respective offices and accommodations; for easy access from the various entrances and approaches, public and private; for security from noise and disturbance; for allowing their form and size to be exactly fitted to the wants of each house; for the purposes of lighting, warming, and ventilating in the most convenient manner; and for making any modifications or alterations in them which may be thought desirable without deranging the general plan and elevations.

It has been thought proper to avoid placing any members' seats under the galleries, as well as any seats whatever behind the woolsack or the Speaker's chair.

From the House of Lords a spacious lobby and corridor will lead directly to the great centre hall, immediately under the centre tower. This hall will be a large apartment, of a circular form, and 60 feet in diameter, and the principal public approach to the committee-rooms from it will be by a broad flight of steps to a large waiting-room on the first floor, from which there will be a direct and immediate access to the committee-rooms of each house, and to the offices connected with them. When the Houses commence their sittings, and the daily business is at an end, the public may retire either by the principal staircase, or by that which leads to Westminster Hall. The central tower will rise in an octangular form, and will be 270 feet in height.

From the central hall, proceeding northward, will be the Commons' corridor and lobby, leading to the House of Commons, with the residence of officers in that division on the east side of New Palace-yard.

Attached to each House of Parliament will be refreshment-rooms and offices, and the approaches of the Sovereign, the members of both houses, and the public; the clerks' and other offices are so arranged as to be wholly independent of each other, with the means of making them entirely or partially in communication.

The members and officers attending committees, it is arranged, may go or return by private staircases communicating with their respective houses and offices.

The whole of the official residences will have separate external entrances and staircases; the principal floor of that for the Speaker will be expressly devoted for state levees or Parliamentary dinners, and will be fitted up on a scale of great splendour.

The libraries and committee-rooms of each house are placed towards the river, for the convenience of light, and freedom from noise and disturbance, and the former are so arranged on the principal floor as to be *en suite*, with the power of extending them at pleasure, by including the adjoining committee-rooms.

The ancient chapel of St. Stephen, the crypt, and cloisters are preserved; over the crypt the spacious apartment will form the inner vestibule to the houses of Parliament, to be called St. Stephen's Hall. This hall will be fitted up in the same style of ornament as the Royal Gallery and the corridors, with the introduction of choice subjects in fresco painting.

Another important feature will also be found in the construction of the two houses for the purpose of a complete and thorough ventillation. This department has been placed under the superintendence of Dr. Reid, who, after a variety of trials of different plans and experiments, has adopted a mode of ventilation by which not only the houses of Parliament but every apartment and office connected therewith may, it is said, be regulated at pleasure. It is proposed that the three great towers shall be made available for this purpose, and from a certain height that the masonry of them shall be hollow, and pierced in several places for the reception and egress of air. According to the state of the wind, air might be received from the Victoria or clock towers, which will occupy the northern and southern extremeties. The form of the Victoria Tower has been already described; the clock tower will also be of the square form, finishing spirally, and of the height of 270 feet. The air thus obtained will be forced by machinery through the vaults under the body of the whole edifice, thence it will be discharged by means of chambers to the body of both houses, extending to the Royal Gallery and the main and entire portions of the buildings. After passing through the various apartments the air will be received by means of perforated ceilings into chambers to be fitted above the roofs, and will be carried off up the central tower.

The works that are already in progress on the eastern or river front are in a great state of forwardness, and will, when completed, extend to 870 feet in length. The ground floor embraces repositories and offices, and the principal one, the Lords' and Commons' libraries, committee-rooms, the conference-hall, and the public and private corridors. The south front will be 340 feet long, that portion next the river being appropriated as the residence of Sir Augustus Clifford, the Usher of the Black Rod. The opposite front, on the northern wing, will comprise the residence of the Speaker of the House of Commons, the Sergeant-at-arms, and other officers.

The external works of the first and principal stories on the river front, including the Lords' and Commons' river entrances, are nearly completed, and the decorations are of the most extensive character. The northern and southern fronts are ornamented with elaborately-sculptured niches in which are placed statues of the various kings who reigned in England prior to the Conquest.

Along the whole eastern front, immediately under the principal floor windows is an ornamented band, on which is displayed in strong relief, in old English characters, the names of every sovereign who has reigned in England since the Conquest, commencing in chronological order with William the Conqueror, and terminating with that of William IV., and above each are the Royal arms of England richly sculptured.—*Standard.*

LAW PROCEEDINGS.

HOARD NUISANCE.

In the Court of Queen's Bench, Friday, December 2nd. Sittings at Nisi Prius at Westminster, before Mr. Justice Coleridge and a Special Jury.)

MURRAY *v.* ELGAR.

The Solicitor-General, Mr. Platt, and Mr. M. Smith, conducted the case for the plaintiff; and Mr. Thesiger, Mr. Dundas, and Mr. Watson, that of the defendant.

This was an action brought by a gentleman residing at No. 16, George-street, Hanover-square, to recover compensation for the injury which he had sustained by reason of the defendant having erected a "hoard," for which some open boarding had been afterwards substituted.

It appeared that the premises occupied by the plaintiff abutted on those occupied by the defendant, who, in 1839, had erected the hoard in question, for which the open boarding had been substituted, within 10 feet of the dining-room windows of the plaintiff. The object was not to recover damages, but to get rid of the nuisance. The servants who had lived in the plaintiff's family before and after the erection of this obstruction, stated that the light in the lower rooms of the house had been considerably diminished, that the walls had become damp in consequence of the free circulation of air beingimpeded, and that the provisions in the larder had frequently been spoiled from the same cause. Several architects and surveyors gave it as their opinion that the value of the house was diminished by one-third, and Dr. Ure stated that he had performed several experiments which convinced him that the light in the plaintiff's dining-room had undergone a diminution of six degrees by the erection of the hoard, and three degrees by the open boards. Mr. Facey corroborated Dr. Ure's evidence, and the medical attendant of the family deposed that Mrs. Murray's health had suffered materially in consequence.

Mr. Thesiger contended that the plaintiff had no right to recover for any loss of prospect or comfort, and that the evidence as to the obstruction of light and air was most unsatisfactory.

Mr. Justice Coleridge having summed up,

The Jury found for the plaintiff, with nominal damages.

PROFESSIONAL CHARGES.

In the Court of Queen's Bench, Friday, December 2nd. (Sittings at Nisi Prius at Westminster, before Mr. Justice Coleridge and a Common Jury.)

DOBSON *v.* CROZIER.

Mr. Platt and Mr. C. Clark were counsel for the plaintiff; and Mr. Whateley and Mr. Petersdorff for the defendant.

This was an action to recover £54 5*s.* 6*d.*, for work and labour done by the plaintiff, who is an architect.

It appeared that the plaintiff had drawn up certain plans and specifications for the erection of a house for the defendant, for which tenders had been offered by builders, but which plan had not been carried into effect. He had subsequently drawn other plans and specifications, from which the house had been erected. The defendant had paid £35 into court, being 5 per cent. on the money expended in carrying into execution the accepted plans. The plaintiff claimed in addition £10 for his trouble in drawing the rejected plans, and some other items, making together the sum of £53, for which the action was brought.

Several surveyors were called for the defendant, who stated it was the custom of the profession to charge 2½ per cent for rejected plans, but they disallowed all items but that charge.

For the defendant it was contended that the plaintiff had not proved that the plans had been rejected through the caprice of the defendant, and therefore it must be taken that the plans were inapplicable.

The learned Judge having summed up, the jury returned a verdict for the plaintiff for 9*l.* 10*s.*, in addition to the money paid into court.

BLACKWALL RAILWAY.—INFRINGEMENT OF PATENT.

In the Court of Queen's Bench, Monday, December 19th. Before a Special Jury.

CURTIS *v.* THE DIRECTORS.

This was an action for the alleged infringement of a patent which had been taken out by the plaintiff, for connecting and disconnecting the draught or ground rope of a railway, with railway carriages, when the rope was in motion. The plan was specially applicable to railways where the carriages were drawn, as on the Blackwall Railway, by means of a rope moved by an engine placed at the spot, towards which the carriages were desired to be drawn. The defendants had adopted a plan for effecting this purpose, which it was alleged was essentially the same as that invented by the plaintiff. The defence was, that the plans were not the same, and that that which was in use on the Blackwall Railway had been suggested to the directors some time before the specification of the plaintiff was published. There was a good deal of evidence given as to the practicability of ever attaching a rope to a railway carriage when the rope was in motion, and much doubt was thrown upon the possibility of such a performance; but a person, named Barn, stated that he had twice done it when in the service of the Blackwall Railway Company; once when, in coming up to London, the rope accidentally got detached, and once at the Limehouse station, when no passengers were in the carriage, for the purpose of an experiment. He, however, said, that it required a "good man" to do it, and the appearance of the witness showed that he came within this expression, in the particular meaning he attached to it. Witnesses having been examined on both sides, the cause, which had occupied the whole of the day, was terminated by the jury interfering, and stating that they were of opinion the powers used by the two parties were not the same, when the plaintiff consented to be non-suited.

ROYAL EXCHANGE.

We hope it may not turn out that there was more of hurry than good speed manifested in the competition for the sculpture that is to adorn the pediment of the portico. Quick work it certainly was, when after being sent in on the evening of the preceding day, the designs were "examined"? on the 25th November, and the ballot-box brought into play instanter; the majority of votes being in favour of Mr. Westmacott—whom rumour had previously marked out as *likely* to be the *fortunate* competitor. After so much has been said relative to the manner in which competitions are managed and mismanaged, it might have been thought that at any rate a little more tact and adroitness would have been employed on this occasion. Whether such was really the case or not, it certainly now *looks* as if it had been a preconcerted affair; for hardly is it possible to suppose that the committee could competently judge off-hand of the merits of the designs as works of art—unless indeed the one chosen was so evidently superior to the two others, as to have no room for doubt or question—which is not very probable. We ourselves saw one of the rejected designs, or rather two different designs by Mr. Watson, the artist who has lately given such public proof of his ability in the bas-relief of the new Commercial Hall in Threadneedle Street; and having seen them, we certainly doubt very much at present if the one "*selected*" be—we will not say of greater, but of equal merit. Upon Hamlet's principle of "Assume a virtue, if you have it not," there might have been the appearance of a little deliberation; there might have been an interval of three or four weeks, during which, artists and those known to be judges of art should have been allowed to inspect the designs, and public opinion in regard to them, so far taken, and taken also into consideration. Possibly the one which is to be executed is the best design, and so too, might the best design have been the winner, had the matter been decided by lottery. If it be worth while to bestow so considerable a sum as Three Thousand Guineas or Pounds on the decoration of the pediment, it was surely worth while to bestow far more scrupulous attention upon the design itself, beforehand than now appears to have been done. However, the Gresham Committee have, in this instance, shown themselves to be men of business and dispatch, who can make up their minds very quickly, without any nonsensical "shilly-shallying." Still, with all our misgivings, we are willing to hope for the best; though as poor Mrs. Nickleby says, "we ought never to be over and above *sanguinary* in our expectations!"

THE FINE ARTS.—THE ROYAL ACADEMY.

On Saturday, the 10th ult., there was a very numerous meeting of the members of the Academy, in Trafalgar-square.

Sir Martin Archer Shee was in the chair; and there were present Sir R. Westmacott, Sir W. Ross, A. Cooper, R. Cooke, H. P. Briggs, W. Etty, C. L. Eastlake, P. Hardwicke, D. Maclise, W. Mulready, T. Unwin, W. Wyon, W. Collins, E. Landseer, C. R. Leslie, J. M. W. Turner, C. R. Cockerell, J. J. Chalon, W. T. Witherington, D. Roberts, E. H. Bailey, and A. E. Chalon, members of the Academy.

At nine o'clock the President commenced the business of the evening, by stating the objects the Academy had in view, by giving those annual rewards to the students who gave tangible proofs of talent, vigilance, and application in the various classes of drawing, painting, sculpture, and architecture; and he then went into a detail of the merits displayed in the respective classes, to all of which, except that of models from the life subject, the medals were cheerfully given by the Council; and the reason for not giving a medal in that class, arose from there only being one candidate, and therefore there could be no competition. The merits of the chalk drawings made from the living models, and from the antique statues, were mentioned in terms of high commendation by the President, who observed emphatically, that the style of drawing these difficult objects had considerably improved within the last two or three years, which he stated arose from the alterations made, deviating from the late method, and which had been judiciously made by the present keeper of the Academy. To the copies in oil from Guido's picture of "Fortune," the President gave high and deserved commendation, as well as to the architectural plans, elevations, and sections of the beautiful Church of Walbrook.

The prizes were then distributed in the following order, viz.:—

To Mr. James Clarke Hook, for the best copy made in the school of painting, the silver medal, with the lectures of the Professors Barry, Opie, and Fuseli.

To Mr. Alfred Rankley, for the next best copy made in the painting school, the silver medal.

To Mr. J. C. Hook, for the best drawing from the living models, the silver medal.

To Mr. John Clayton, for the best drawings of the ground plan, sections, &c., of St. Stephen's Church, Walbrook, the silver medal.

To Mr. James Harwood, for the best drawings from the antique, the silver medal.

To Mr. Alfred Gatley, for the best model from an antique statue, the silver medal.

After the delivery of the prizes, the President concluded the public business of the evening with an address from the chair, which was replete with the soundest practical observations upon the state, condition, and prospects of the arts in this country. We regret that our limits do not allow us to give a full report of this able and eloquent discourse; but amongst the points he touched upon with energy and feeling were, that unworthy and groundless prejudice that still remains in the minds of a few of the noble and wealthy classes in England, which would place foreign modern arts far above that of Great Britain, even at the present day. This morbid desire to set up every country above their own in matters of an intellectual nature, was far more commonly entertained some years since in England than it has been of late; we have done our part in demolishing this unnatural, this monstrous doctrine, and it has been damaged irretrievably. After the President had clearly and with much energy pointed out the gross absurdities and contradictions of the few anti-national connoisseurs who still exist, he properly noticed another unnatural practice which militates against the arts of the United Kingdom—namely, the vituperation poured forth *pleno flumine* by the minor press, generally, against the native artists and their works. The President went into many topics professionally interesting, and, on concluding his address, was warmly applauded.

The general assembly then proceeded to appoint officers for the ensuing year, when Sir Martin Archer Shee was unanimously elected President.

Council, New List.—Messrs. Charles Barry, George Jones, Alfred E. Chalon, and Thomas Phillips.

Old List.—Messrs. Philip Hardwick, David Roberts, John James Chalon, and William Mulready.

Visitors in the Living Model Academy, New List.—Messrs. Edward H. Bailey, Alfred E. Chalon, Richard Cook, and William Frederick Witherington.

Old List.—Messrs. Charles Robert Leslie, William Mulready, Thomas Uwins, and W. Wyon.

Visitors in the School of Painting, New List.—Messrs. Henry P. Briggs, Charles L. Eastlake, Charles Robert Leslie, and Thomas Uwins.

Old List.—Messrs. W. Collins, W. Etty, Edwin Landseer, and David Roberts.

Auditors re-elected.—Messrs. William Mulready and J. M. W. Turner, and Sir R. Westmacott.

THERMOGRAPHY.

Art of Copying Engravings, or any Printed Characters from Paper on Metal Plates; and on the Recent Discovery of Moser, relative to the Formation of Images in the Dark. By Mr. Robert Hunt. *Read at the Meeting of the Cornwall Polytechnic Society, on the 8th Nov. of which excellent Society Mr. Hunt is the secretary.*

The Journal of the Academy of Sciences of Paris, for the 18th of July, 1842, contains a communication made by M. Regnault, from M. Moser, of Konigsberg, "Sur la formation des images Daguerriennes;" in which he announces the fact, that "*when two bodies are sufficiently near, they impress their images upon each other.*" The Journal of the 29th of August contains a second communication from M. Moser, in which the results of his researches are summed up in 26 paragraphs. From these I select the following, which alone are to be considered on the present occasion:—"All bodies radiate light, even in complete darkness.—This light does not appear to be allied to phosphorescence, for there is no difference perceived whether the bodies have been long in the dark, or whether they have been just exposed to daylight, or even to direct solar light.—Two bodies constantly impress their images on each other, even in complete darkness. However, for the image to be appreciable, it is necessary, because of the divergence of the rays, that the distance of the bodies should not be very considerable.—To render the image visible, the vapour of water, mercury, iodine, &c. may be used.—There exists *latent light* as well as latent heat."

The announcement at the last meeting of the British Association of these discoveries, naturally excited a more than ordinary degree of interest. A discovery of this kind, changing, as it does, the features, not only of the theories of light adopted by philosophers, but also the commonly received opinions of mankind, was more calculated to awaken attention than anything which has been brought before the public since the publication of Daguerre's beautiful photographic process. Having instituted a series of experiments, the results of which appear to prove that these phenomena are not produced by *latent light*, I am desirous of recording them.

I would not be understood as denying the absorption of light by bodies; of this I think we have abundant proof, and it is a matter well deserving attention. If we pluck a Nasturtium when the sun is shining brightly on the flower, and carry it into a dark room, we shall still be enabled to see it by the light which it emits. The human hand will sometimes exhibit the same phenomenon, and many other instances might be adduced in proof of the absorption of light; and I believe, indeed, of the principle that light is latent in bodies. I have only to show that the conclusions of M. Moser have been formed somewhat hastily, being led, no doubt, by the striking similarity which exists between the effects produced on the Daguerreotype plates under the influence of light, and by the juxtaposition of bodies in the dark, to consider them as the work of the same element.

1. Dr. Draper, in the Philosophical Magazine for September 1840, mentions a fact which has been long known, that "if a piece of very *cold* clear glass, or what is better, a *cold* polished metallic reflector, has a little object, such as a piece of metal, laid on it, and the surface be breathed over once, the object being then carefully removed, as often as you breathe again on the surface, a spectral figure of it may be seen, and this singular phenomenon may be exhibited for many days after the first trial is made." Several other similar experiments are mentioned, all of them going to show that some mysterious molecular change has taken place on the metallic surface, which occasions it to condense vapours unequally.

2. On repeating this simple experiment, I find that it is necessary for the production of a good effect, to use dissimilar metals; for instance, a piece of gold or platina on a plate of copper or of silver, will make a very decided image, whereas, copper or silver on their respective plates give but a very faint one, and bodies which are bad conductors of heat placed on good conductors, make decidedly the strongest impressions when thus treated.

3. I placed upon a well polished copper plate, a sovereign, a shilling, a large silver medal, and a penny. The plate was gently warmed by passing a spirit lamp along its under surface: when cold, the plate was exposed to the vapour of mercury; each piece had made its impression, but those made by the gold and the large medal were most distinct; not only was the disc marked, but the lettering on each was copied.

4. A bronze medal was supported upon slips of wood, placed on the copper, one-eighth of an inch above the plate. After mercurialization, the space the medal covered was well marked, and for a considerable distance around the mercury was unequally deposited, giving a shaded border to the image.

5. The above coins and medals were all placed on the plate, and it was made too hot to be handled, and allowed to cool without their being removed: impressions were made on the plate in the following order of intensity, gold, silver, bronze, copper. The mass of the metal was found to influence materially the result: a large piece of copper making a better image than a small piece of silver. When this plate was exposed to vapour, the

results were as before (3, 4). On rubbing off the vapour, it was found that the gold and silver had made permanent impressions on the copper.

6. The above being repeated with a still greater heat, the image of the copper coin was, as well as the others, most faithfully given, but the gold lead, and silver only made permanent impressions.

7. A *silvered* copper plate was now tried with a moderate warmth (3). Mercurial vapour brought out good images of the gold and copper; the silver marked, but not well defined.

8. Having repeated the above experiments many times with the same results, I was desirous of ascertaining if electricity had any similar effect; powerful discharges were passed through and over the plate and discs, and it was subjected to a long continued current without any effect. The silver had been cleaned off from the plate (7), it was now warmed with the coins and medals upon it, and submitted to discharges from a very large Leyden jar; on exposing it to mercurial vapour, the impressions were very prettily brought out, and strange to say, spectral images of those which had been received on the plate when it was silvered (7). Thus proving that the influence, whatever it may be, was exerted to some depth in the metal.

9. I placed upon a plate of copper, blue, red, and orange coloured glasses, pieces of crown and flint glass, mica, and a square of tracing paper. These were allowed to remain in contact half an hour. The space occupied by the red glass was well marked, that covered by the orange was less distinct, but the blue glass left no impression: the shapes of the flint and crown glass were well made out, and a remarkably strong impression where the crown glass rested on the tracing paper, but the mica had not made any impression.

10. The last experiment repeated; after the exposure to mercurial vapour, heat was again applied to dissipate it, the impression still remained.

11. The experiment repeated, but the vapour of iodine used instead of that of mercury. The impressions of the glasses appeared in the same order as before, but also a very beautiful image of the mica was developed, and the paper well marked out, showing some relation to exist between the substances used and the vapours applied.

12. Placed the glasses used above (9, &c.), with a piece of well smoked glass, for half an hour one-twelfth of an inch below a polished plate of copper. The vapour of mercury brought out the image of the smoked glass only.

13. All these glasses were placed on the copper, and slightly warmed; red and smoked glasses gave, after vaporization, equally distinct images, the orange the next, the others left but faint marks of their forms; polishing with tripoli and putty powder would not remove the images of the smoked and red glasses.

14. An etching, made upon a smoked etching ground on glass, the copper and glass being placed in contact. The image of the glass only could be brought out.

15. A design cut out in paper was pressed close to a copper plate by a piece of glass, and then exposed to a gentle heat; the impression was brought out by the vapour of mercury in beautiful distinctness. On endeavouring to rub off the vapour, it was found that all those parts which the paper covered amalgamated with mercury, which was removed from the rest of the plates: hence there resulted a perfectly permanent white picture on a polished copper plate.

16. The coloured glasses before named (9, 12), were placed on a plate of copper, with a thick piece of charcoal, a copper coin, the mica, and the paper, and exposed to fervent sunshine. Mercurial vapour brought up the images in the following order—smoked glass, crown glass, red glass, mica beautifully delineated, orange glass, paper, charcoal, the coin, blue glass; thus distinctly proving, that the only rays which had any influence on the metal, were the calorific rays. This experiment was repeated on different metals, and with various materials, the plate being exposed to steam, mercury, and iodine; I invariably found, that those bodies which absorbed or permitted the permeation of the most heat, gave the best images. The blue and violet rays could not be detected to leave any evidence of action, and as spectra imprinted on photographic papers by light which had permeated these glasses, gave evidence of the large quantity of the invisible rays which passed them freely, we may also consider those as entirely without the power of effecting any change on compact simple bodies.

17. In a paper which I published in the *Philosophical Magazine* for October, 1840, I mentioned some instances in which I had copied printed pages and engravings on iodized paper, by mere contact and exposure to the influence of the calorific rays, or to artificial heat. I then, speculating on the probability of our being enabled, by some such process as the one I then named, to copy pictures and the like, proposed the name of Thermography, to distinguish it from Photography.

18. I now tried the effects of a print in close contact with a well-polished copper plate. When exposed to mercury, I found that the outline was very faithfully copied on the metal.

19. A paper ornament was pressed between two plates of glass, and warmed, the impression was brought out with tolerable distinctness on the under and warmest glass, but scarcely traceable on the other.

20. Rose leaves were faithfully copied on a piece of tin plate, exposed to the full influence of sunshine, but a much better impression was obtained by a prolonged exposure in the dark.

21. With a view of ascertaining the distance at which bodies might be copied, I placed upon a plate of polished copper, a thick piece of plate glass, over this a square of metal, and several other things, each being larger than the body beneath. These were all covered by a deal box, which was more than half an inch distant from the plate. Things were left in this position for a night. On exposing to the vapour of mercury, it was found that each article was copied, the bottom of the deal box more faithfully than any of the others, the grain of the wood being imaged on the plate.

22. Having found, by a series of experiments, that a blackened paper made a stronger image than a white one, I very anxiously tried to effect the copying of a printed page or a print. I was partially successful on several metals, but it was not until I used copper plates amalgamated on one surface, and the mercury brought to a very high polish, that I produced any thing of good promise. By carefully preparing the amalgamated surface of the copper, I was at length enabled to copy from paper line-engravings, wood-cuts, and lithographs, with surprising accuracy. The first specimens produced (which were submitted to inspection), exhibit a minuteness of detail and sharpness of outline quite equal to the early Daguerréotypes and the photographic copies, prepared with chloride of silver.[1]

The following is the process at present adopted by me, which I consider far from perfect, but which affords us very delicate images. A well polished plate of copper is rubbed over with the nitrate of mercury, and then well washed to remove any nitrate of copper which may be formed; when quite dry, a little mercury taken up on soft leather or linen is well rubbed over it, and the surface worked to a perfect mirror. The sheet to be copied is placed smoothly over the mercurial surface, and a sheet or two of soft, clean paper being placed upon it, is pressed into equal contact with the metal by a piece of glass, or flat board; in this state it is allowed to remain for an hour or two. The time may be considerably shortened by applying a very gentle heat for a few minutes to the under surface of the plate. The heat must on no account be so great as to volatilize the mercury. The next process is to place the plate of metal in a closed box, prepared for generating the vapour of mercury. The vapour is to be slowly evolved, and in a few seconds the picture will begin to appear; the vapour of mercury attacks those parts which correspond to the white parts of the printed page or engraving, and gives a very faithful but somewhat indistinct image. The plate is now removed from the mercurial box, and placed in one containing iodine, to the vapour of which it is exposed for a short time; it will soon be very evident that the iodine vapour attacks those parts which are free from mercurial vapour, blackening them. Hence there results a perfectly black picture, contrasted with the grey ground formed by the mercurial vapour. The picture being formed by the vapours of mercury and iodine, is of course in the same state as a Daguerreotype picture, and is readily destroyed by rubbing. From the depth to which I find the impression made into the metal, I confidently hope to be enabled to give to these singular and beautiful productions a considerable degree of permanence, so that they may be used by engravers for working on. It is a curious fact, that the vapours of mercury and of iodine attack the plate differently, and I believe it will be found that vapours have some distinct relation to the chemical or thermo-electrical state of the bodies upon which they are received. Moser has observed this, and attributes the phenomena to the colours of the rays, which he supposes to become latent in the vapour on its passing from the solid into the more subtile form. I do not, however, think this explanation will agree with the results of experiments. I feel convinced that we have to deal with some thermic influence, and that it will eventually be found that some purely calorific excitement produces a molecular change, or that a thermo-electric action is induced, which effects some change in the polarities of the ultimate atoms of the solid.

These are matters which can only be decided by a series of well conducted experiments. Although attention was called to the singular manner in which vapours disposed themselves on plates of glass and copper, two years since by Dr. Draper, Professor of Chemistry at New York, and about the same time to the calorific powers of the solar spectrum, by Sir John Herschel, and to the influence of heat artificially applied, by myself (17), yet it is certainly due to M. Moser of Konigsberg, to acknowledge him to be the first who has forcibly called the attention of the scientific world to an inquiry which promises to be as important in its results as the discovery of the electric pile, by Volta.

[1] The first faithful copy of the lines of a copper plate engraving was obtained by Mr Cantabrano, who has since succeeded in procuring some tolerable specimens on amalgamated copper which cannot be rubbed off.

NOTES ON EARTH WORK, EXCAVATION, CUTTING, AND FORMING EMBANKMENT UPON RAILWAYS.

Article IV.—Superintendence, Accounts, and Measurements.

"Modern practice has reduced it to a price per cubic yard."
Professor Vignoles's Lecture, Dec. 1841.

In pursuance of my promise given at the conclusion of my former paper, I shall now attempt to give a description of the methods in use during the execution of railways, as regards the supervision, both on the part of the Company and contractor. First, then, as to the engineering staff; we have parliamentary and consulting engineers, engineer in chief, resident, assistant, and sub-engineers, but the duties of the resident and assistant it will only be necessary for me to notice. The resident controls the whole line and the assistants, and confers with the Directors at all their meetings for finance, and when the line exceeds 50 miles in length, the duties will be so multiplied that two will be requisite. The assistants are subordinate to the resident, and have generally a division of 10 miles each, or perhaps a length of, say three contracts. The duties of an assistant is to observe that the works are executed according to plan, and that the materials are of proper quality, and if not so, to complain, first to the contractor, and if not attended to, then to the resident; to allow no change to be made in the dimensions without the sanction of the resident, and if any change is ordered, to ascertain the difference for or against the contractor jointly with him or his agent, to enter these measurements in a book, and to make a return monthly to the resident, as also of all materials received on the Company's account, as rails, chairs, keys, sleepers, blocks, &c. He is also to make a return each fortnight, of the number of men employed by the contractor, to measure works for monthly payments, and price them by the schedule attached to the contract. In taking the measurements, he will much facilitate his work by making them as near as possible to given points, so as to save re-measurements. He is also to see that all levels are executed with reference to bench marks and gradients given, and to preserve the centre or trig line, especially in curves, and to give the half width of railway, and to see that no more land is enclosed than has been purchased, and finally to be in frequent communication with the resident, and if any thing unexpectedly occurs, to lose no time in communicating it. From the above statement of duties, it will be seen that great responsibility is often placed on the shoulders of the assistant, partly owing to the distance that separates him from the resident.

The accounts in detail are in the province of the contractor, which will be hereafter considered. The assistant should have a knowledge of measuring land and artificer's work, as at the stations on the line he is brought into communication with slaters, joiners, masons, plumbers, &c. The supervision of a contract on the part of a contractor will consist of a superintendent, clerk, timekeepers, and foreman over each department of artificers. The superintendent sets out the works, and sub-lets them to the various gangers and butty gangs, and measures and prices their work; he also measures with the assistant engineer for the monthly payments. The clerk keeps the books, &c. and invoices. The foremen superintend their own trade, and examine the goods sent to the works, with the invoice, both as regard quality and quantity; they also send in a weekly return of all the men's time individually, and the nature of his employment, whether on extra or contract work, and any materials sent to other works, each individual workman making a return to him on a printed form provided for the purpose. The timekeepers collect the names of the ganger's men employed at occasional daywork, and count the number of men in each gang four times daily, and take an average as to the number employed for the day. One day is retained in hand from each man employed at daywork, until he is discharged, the wages being paid on the Saturday, although not for that day, but the Saturday preceding, counting from each Friday night.

I will, perhaps, better explain myself by giving, as it were, instructions to a set of men on a contract as to the manner they should adopt in keeping the accounts:—then as to the clerk, he is to debit the ganger's account, with the weekly men received, and enter to his credit the quantities and prices he is to have for his work; to fill up a weekly summary, showing how many men have been employed upon each separate description of work, and to render a perfectly separate account of day work. With respect to payments, he is to pay no task man without express sanction of superintendent, and to pay no day man except on a Saturday, unless he discharge himself entirely from the works, when he is to pay the back day kept in hand. He is to receive the invoices after they are examined by the foreman, whose duty it is to receive the goods. The invoices to be filed until the monthly or quarterly bills are delivered for examination. The invoices are to be copied into the day book, materials sent to or received from other works to be entered in books expressly for that purpose, bricks, lime and sand will be kept in separate accounts, backed with the party's name who supplies each material. No goods to be sent by tradesmen without an order, and to have a return ticket on delivery, for both of which forms are provided. Timekeepers to deliver to the desk every evening, the correct time and name of every man employed at daywork; also daily, the name of every ganger, the number of men, where at work, and the description of work. Any claim by the ganger for daywork not to be allowed unless rendered to the office as the regular daymen, and he must apply for payment the next Saturday, as it will not be paid at a subsequent period; and his account for taskwork must be settled monthly.

The superintendent lets and measures the works, and is responsible for the levels, and he is in fact the whole executive, the contractor being the capitalist or speculator. In the preceding account, no notice is taken of truck system, tommy shops, menage shops, or subsist money, or any of the tricks of contractors without capital, or such as those would be sure to have the lowest estimate; but the proceedings of a wealthy and reputable contractor are recorded, and from having seen service in both camps, I can bear testimony as to the good effects, both morally and physically, of the latter method of proceeding. The facility now given to contractors of keeping accounts open for an indefinite time, would be much checked, if engineers would not certify contracts completed, until the contractors previously lodged with them copies of all their extra claims.

With respect to measurement of works in progress, the various tables published by M'Neil, Day, Bidder, and the prismoidal formula, &c., are perfectly inapplicable, from the broken nature of the ground, it assuming shapes so various and uncouth at the different benches, gullets and levels; it is, therefore, necessary to take the dimensions on the ground, and by computation, ascertain the cubic contents. A considerable difference of opinion exists as to the modes of so doing, some using the decimal, and others the duodecimal measures; the former gives the contents in yards by multiplication, and the latter gives greater facility for the application of practice, or the division by aliquot parts; and the total can easily be converted into yards by dividing the number of cubic feet in a yard. In the one case, all dimensions are taken in feet and inches, and in the other, they are taken by a yard and decimal parts, the yard being divided decimally into a hundred divisions; this latter method is most used by old practitioners: but feet and inches are now being more used than formerly. The dimensions are recorded in two columns; one for the length, breadth, and depth, placed one over the other always in the same succession: the other column being left for the cubic contents of each dimension as it is squared, so as to make the addition of the several items into a total more easy. The dimensions of finished cuttings are taken at each chain's length, by a line stretched across on the natural surface of the ground, and a staff held in the centre, by an assistant, and a mean of the two ends taken for the depth. The width is measured half way up each slope in the centre of each chain. The length is measured along the centre of the cutting. The dimensions of each hole in broken work is taken similarly, but is recorded as only on account, and at a subsequent measurement it is retaken from a certain fixed point or chain in the section, which the measurement book will tell if kept on a uniform plan.

In making the monthly return of work executed, all previous measurements are annulled in toto; and the return made is the total quantity done, and not that that is done between each measurement. When a work is very rugged, it is usual to take the measurement of the embankment, and not the cutting, on account of the fewer dimensions. The cuttings are measured generally every fortnight, the intervening time being subsist weeks, when the pay is on account, from the timekeeper's return; and in some cases the number of wagons are computed as a check. The persons who act as timekeepers, are generally of the class that has seen better days; the excavators are a migratory horde, they are a collection of the agricultural labourers, who are more spirited than their fellow-countrymen, and who have left their native locality to better their condition; so that in works of this sort, trusting too much to the honour of such men will not do; and the more checks there are the better, or one stands the chance of knowing experimentally the meaning of the term "sloping," which by this time is fully known in France.

I have said nothing as to the mode in which the directors, engineer, and secretary, keep a check on each other; I think, however, that it is done by a system of sub-committees of finance, and the division of the line into districts, and that no monies are paid by the banker without the signatures of three of the directors and the secretary; being on an analogous plan to that adopted in olden times by corporate bodies—"The wardens each to have a key and a chest with three locks, and each to keep a key." I hope some one who has had a seat at the board will supply the information, as also the form of each printed paper used in each department—say engineer's department, printed forms for return of number of men, specification of rails, and general specification for works, number of yards done on each contract, return for each subdivision of the line, and schedule of prices, and tickets of return for materials received, and letter heads. In superintendent of line, a pass book for free riding on the service of the company, memorandum of coaching department, code of signals, instructions and duties of guards, general regulations for police, superintendent, inspectors, constables, switchmen and gatekeepers; instructions for the use of signal flags. Police department, return of train before or after time, number of engine, name of driver, number and description of carriages, trucks, wagons, horse boxes, and inspectors' remarks, and occurrences at the different stations, viz., number of coaches of 1st, 2nd, or 3rd class, and carriage trucks, vans, wagons, and mails leaving each station and left behind; also, a return of the name of upper guard, whether delayed by passengers or water, with the time of arrival, when due and despatched from each station. There are also a return of absentees, whose wages are suspended, viz., number of column, name, quality, where stationed, and cause of absence, and amount of wages. In addition to the above related departments, there are the printed time tables, and the ticket system; of colours for the different classes, and whether going east, west, north, to notice the returns or accounts rendered by police, when a line is south, or on the up or down trains.

In conclusion, the mention of defalcations must not be omitted that have taken place in the staff of the companies, which have amounted to upwards of six cases, and those invariably in the secretary's department; and in no one case am I aware that they have been brought to trial. The engineers generally come in for the greatest share of odium when works are unsuccessful, but I think the blame ought to be divided between the solicitor, secretary, and other officers, or the committee, which is indefinite enough. The engineer is of necessity obliged to be somewhat acquainted with his business, as influence and patronage will not so exclusively prevail as in other departments. I have known a line of railway where a quondam director slid into the office of superintendent, with £500 a-year; he was originally a druggist, having a seat at the board, which the sub-engineer had not; he was enabled to coerce him to do his duty, with no extra pay, he was a fluent speaker, and often saved the directors from attack; he could not, however, retain his ground, and both he and the body of directors acted shabbily to their employees, and illegally to their employers, the unfortunate shareholders. I may go on for some time longer, but am afraid of the editorial pruning hook; so for the present, conclude.

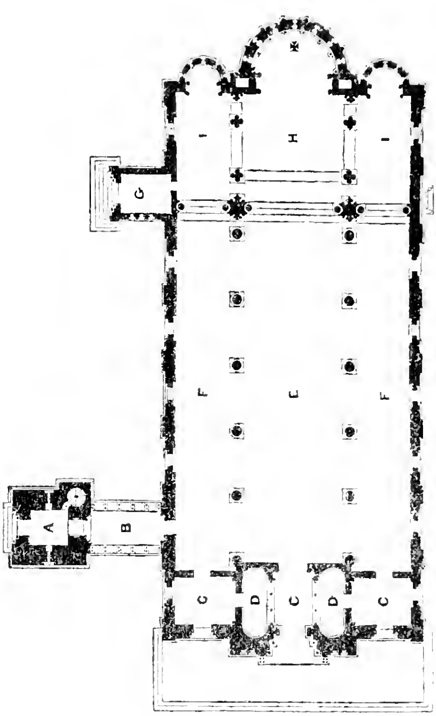
St. Ann's, Newcastle-on-Tyne. O. T.

REVIEWS.

COMPANION TO THE ALMANAC, FOR 1843.

On returning to this publication, we might dispense with prefatory remark; nevertheless, we have one to make by way of suggestion to its publishers, viz., that as they must now afford materials enough for the purpose, were all the architectural chapters from the commencement of the series collected together and reprinted, with such alterations and additions as might be found requisite, they would form a very useful and convenient volume—one that would to a certain extent serve as a Pocket Companion and Architectural Guide to the Tourist. As a sequence to this suggestion, we will venture another to publishers abroad, which is, that an "*Annuaire*" of new buildings, &c., for France and Germany—one for each country—is a desideratum.

Messrs. Wyatt and Brandon here make their début in the "Companion," with some éclat; there being three different buildings by them, and one of them very superior for a building of the kind, although—perhaps it would be nearer the truth to say *because*—it is in that picturesque style the Lombardic, against which, however, the Camden Society folks object, because, forsooth, it is not sufficiently "Christian" for their strait laced notions, upon matters that are purely conventional, and have nothing whatever to do with genuine religion. To object—otherwise than as taste is concerned, against the abandonment of the usages observed by our Roman Catholic builders, is surely ultra-squeamishness, after we have abandoned Romanism itself, with its idle pomposity and all its trumpery. Puseyism and Camdenism seem to have of late completely turned some people's brains. Instead of entering into frivolous, hair-splitting objections, we are well content with Wilton Church, on its own architectural merits, which are no ordinary ones; for while the exterior is strikingly picturesque in composition and design, the interior will, when completed, be quite a model of its kind—simple, yet beautiful and varied in its plan, and tasteful in its decorations; and not only with much to produce effect, but with nothing to counteract it, for there will be no galleries—at least no side galleries—which always give a sort of play-house look to a church; and which, even if capable of being so treated, never are made architectural in appearance, but always so as to cut up and encumber. Still, it must be confessed, that galleries accord very well with Professor Hosking's principle, that in churches "the largest number of persons must be brought within the smallest space!"—it is a wonder he did not add, "and at the cheapest rate." The three apses at the altar end of Wilton Church will be filled with stained glass, and for the further decoration of those recesses, which contribute so much to effect, it is in contemplation to paint their ceilings or semi-domes in fresco, but whether with subjects, or merely ornamental compositions as in the Temple Church, is not stated. Even the strait-laced "Ecclesiologist," though it protests against "the introduction of a foreign style in church architecture," as an evil that ought to be put a stop to at once, allows that Wilton Church is at least "good of its sort." Almost the only other church with regard to which the Companion enters into description, is the one now building by Mr. Poynter, in Broadway, Westminster, in the style of the later period of early English. Its internal dimensions are about 95 by 51 feet, exclusive of a spacious apsis at the east end; but as there are, unfortunately, to be galleries, we fear we must not anticipate any great excellence of architectural



Ground Plan of Wilton Church.

character. The tower and spire, however, rising together to the height of 200 feet, and placed campanile fashion at the north-west angle of the front, will be a very good and bold feature in the exterior. Of Mr. Pugin's Catholic Church, near the Blind School, no further mention is made, but we suppose that when completed, it will be fully described, and at present it certainly promises well—for there is much excellent detail in doors and windows, some of which will be rather highly decorated, although the general material is only brick—but homely as it is, even that is better than what has been not unaptly called the "stone and starvation" style.

The Wesleyans seem to be patronizing architecture; their College or "Theological Institution" at Richmond, is an extensive stone structure in the Tudor style, and with some novelty in its design; but the wood-cut view of it does not show it to any great advantage, the shadowed parts being indistinct and confused. Whether the execution be as satisfactory as the design, we pretend not to say; but as far as the general character of its façade goes, it appears to be a building that would not disgrace either of our universities. Mr. Cockerell's Sun Assurance Office is spoken of, upon the whole, with commendation, yet not without some exceptions being made to it. The first floor windows are objected to as being rather poor and trivial in design, and as requiring further enrichment which might have been so applied as to fill up the plain spaces or panels between the rusticated piers in which they are set. Had this been done, they would certainly have been more important features in the composition, but not at all more so than their situation requires; and they would at the same time have given greater originality of character to the whole. The *ensemble*, too, would have been more in keeping. The interior of the new libraries at Cambridge—that is, of the north wing, the only portion as yet finished—another work by the same architect, is also described as being greatly better than the exterior, and the principal room is said to be a very noble apartment. Another building at Cambridge, and of which a tolerably full account is here given—which is certainly not the case in Le Keux's Memorials of Cambridge, there being there scarcely a syllable relative to it—is that for the new county courts, by Messrs. Wyatt and Brandon. The façade consists of an Italian Doric order in pilasters, comprising a lesser one of insulated columns from which spring arches, after the manner of a Venetian window. Of these the five centre ones are open so as to form a recessed loggia or arcade, and produce a bold effect of light and shade. The idea is borrowed from Palladio's Basilica at Vicenza, but also exhibits, as is here remarked, a considerable degree of improvement upon the original; though, to talk of improving upon anything by Palladio, that may seem little less than treason to those who hold his works to be the *ne plus ultra* of refined taste. Of the "Brunswick Buildings" at Liverpool, some account was given in our last volume, at page 278, therefore we need here say no more than that the view in the Companion fully bears out the description of it, and shows it to be an exceedingly handsome piece of architecture.

Under the head of "Railways of Great Britain" we have a brief record of the progress of railways since Nov. 1, 1841, by which it appears that, from that time to the present, there is a total extent of 176¾ miles more brought into operation.

An Encyclopædia of Architecture, Historical, Theoretical, and Practical. By JOSEPH GWILT. Illustrated by more than 1000 engravings on wood. In one thick volume, 8vo, 1089 pp. London, 1842. Longman & Co.

As one of a series of similar works devoted to separate branches of study, and which has been stamped by public favour, and as a useful and economic compendium for the student, this Encyclopædia will, no doubt, prove a successful publication. Its contents, however, are so multifarious, some of them bearing upon matters which are but very remotely connected with architecture properly so termed, that it is to this last department we must confine ourselves for the present. And we begin by remarking that one great disadvantage attending works of the kind is that, however satisfactorily they are executed, as regards their main purpose, namely, the instructing those who have yet to learn, they are apt to disappoint those who are already familiar with the subject treated of, and of course acquainted beforehand with the substance of the information thus collected together. Allowance must, therefore, be made for want of novelty, since the whole ground must be gone over again, and novelty can be displayed only in the writer's views and opinions, and in his corrections of or additions to what has previously been said by others. We must, accordingly, restrict our observations to the architectural portion of the work, but to those opinions thrown out in it, which come immediately from Mr. Gwilt as their author; for it is these alone that can be made to serve as characteristic specimens, in a mere notice like the present, of so extensive a work.

One thing which is clearly enough apparent is, that Mr. Gwilt has not written *ad captandum*, at least not as far as the profession are concerned, for he expresses himself more than once by no means very encouragingly in regard to the present state of the art in this country, especially as compared with what it is in France. We do not quarrel with him for uttering such opinion, unpleasant as it may be, provided it be uttered in sincerity; but it is to be regretted that, as he has not scrupled to make so severe an allegation, he did not also allege some of the grounds on which it is formed. Possibly he may mean, not that there is greater architectural talent in France, but that greater and more frequent opportunities are afforded it in that country than in our own, where, according to him, it is rather checked than encouraged by the government;—which qualification would have softened the asperity of the censure. Very far be it from us to object to the expression of censure, for it is that which gives value to praise, and which produces improvement by holding up faults for correction; still we do not exactly approve of that species of it which deals in such vague generalities that it is hardly possible to meet and combat it. We own that too many opportunities are made mere jobs of in this country—that interest and favouritism too frequently supersede merit, and that false economy, which often turns out in the end to be very expensive, sadly maims many of our public undertakings in architecture; but we are also of opinion that there is talent among us that would fully vindicate our national reputation in art, were it but drawn out, or rather permitted to display itself uncramped, or even with some tolerable degree of freedom. When we look at what has been done in various parts of the country within the last few years, we perceive, upon the whole, improvement—certainly no falling off, and with regard to ability in Gothic architecture, we stand very far superior to any of our continental neighbours.

We do not dissent, however, very much from Mr. Gwilt, when he tells us that "the splendour of the government offices in this country, seems to be in an inverse ratio from the renown of the department;" in instance of which he refers us to the Admiralty and the "Treasury jumble of buildings;" to which he might have added the Custom House—a most miserable affair in point of architecture, and also the Mint, which has no merit, certainly not that of character, to recommend it. It is notorious that his opinion of the National Gallery is the reverse of favourable, as is likewise that which he entertains of the London University; nor do we suppose that he thinks very highly of either the Post-office, or the British Museum, for though he has not expressly censured, neither has he expressly excepted them from the rest. But it is rather, we trust, with reference to the past than to the immediate present, that there is or henceforth will be room for complaining of the indifference betrayed on the part of the government and those in power, towards architecture and the other fine arts. Something like a public voice in their behalf has lately made itself heard amidst all the never-ceasing din and squabbling of politics, and the daily palavering of the public press. The erection of such a noble fabric as the new Houses of Parliament will at least wipe off some of the reproach justly incurred by many other structures, national in their purposes, though of the nation most unworthy; and it may further be anticipated, that the schemes in contemplation for its internal embellishment, will give a powerful and lasting impulse to other branches of art. We will not risk our credit by predictions that may possibly be falsified by the event: fresco-painting may not succeed here, as far as by success is meant the satisfying public expectation and public taste; but it is a good augury, *ad interim*, that any discussion on the subject of it should have been treated as matter of public interest.

There is no difficulty in interpreting Mr. Gwilt's "expressive silence" in regard to Buckingham Palace, in the section devoted to that class of buildings, more especially as he is exceedingly chary indeed of any thing like praise towards another structure, which some have thought they could not extol too magniloquently. "We regret," he says, "that in this country we can offer no model of a palace for the student. Windsor Castle, with all its beauties, which, however, consist more in site and scenery than in the disposition of a palace, will not assist us." Ungracious and captious as this opinion may appear to many, it does not at all shock us. What we object to is, not the opinion itself, but to the *ipse dixit* tone in which it is uttered, without explanation on the part of the writer, so that we are at a loss to know what it is he most objects to in it; whether it be the plan and arrangement chiefly, or the style and the design.[1] We almost suspect

[1] As neither Mr. Poynter nor Mr. Britton has attempted to enter into a critical examination of the edifice as it came from Sir Jeffrey's hands—

that it is to these last he objects, and that he is disposed to class Sir Jeffry Wyatville with another "incompetent architect," for he has omitted his name as well as that of Wilkins in his list of architects, as he has likewise that of James Wyatt; which omissions cannot have been other than intentional, and are therefore peculiarly significant. However lightly we may now estimate him, James Wyatt is most indisputably an historic name in the annals of English architecture, and very far less of a mere shadow and *nominis umbra*, than some of those who are registered and catalogued by the historiographers of art, and of whom there is very little more than their dates to record. The name of Schinkel ought to have been inserted, unless the list was actually printed before his death was known in this country, which as it comes nearly at the end of the volume, we can hardly suppose to have been the case. We are aware that Schinkel is no favourite of Mr. Gwilt's; but favourite or not, his fame has spread throughout Europe; and if names so distinguished are to be omitted at pleasure, we may perhaps, ere long, see that of Palladio expunged from a table of eminent architects.[2] At any rate the precedent is an unfortunate one.

It cannot be expected that we should pretend to go regularly through a work so comprehensive, or have as yet thoroughly examined it; therefore—for the present at least—our readers must be content with our pointing out some of the passages and remarks which we noted in looking over the work. Among them are some which hit hard at the new Royal Exchange, animadverting on the want of judgment manifested, in leaving that portion of it which is intended for the Exchange itself, uncovered; which, however, he admits to be a matter of taste; "for if our merchants prefer exposure to the inclemency of the seasons, it is not our business to complain of their fancy." But that is not all; for after speaking of the Bourse at Paris, as an excellent model for buildings of that class, he adds, "the merchants and city of London disgrace themselves by allowing [only] £150,000 for a similar purpose here; and even for this sum they cut up their building into little slices, to reimburse themselves by rents for the miserable outlay. So much for the spirit and liberality of the British merchant!" Though that spirit will most assuredly not obtain for its writer the freedom of the city of London, or any other civic honours, we freely vote it our approbation, since we must own that, compared with the flourishing promises that bid us look for a structure worthy of the first commercial city in the world, the Royal Exchange has sunk down into insignificance.[3]

With equal justice do the Church Commissioners come in for a very severe reprimand from Mr. Gwilt, who, in one place, says, "if ever a death blow was aimed at the art, that was done by the commissioners for building the recent new churches;" and in another, he talks of "true honest churches, one whereof is better than a host of the brick Cockney-Gothic things that are at present patronized, wherein the congregations are crammed to suffocation and not accommodated." It is, indeed, mortifying to reflect that although they have afforded employment to numbers in the profession, the buildings alluded to have not at all benefitted architecture itself.

But what shall we say of the severe strictures at page 642, on the present modes of architectural drawing, which contain so much for consideration that they would afford us matter for a separate paper? That in both exhibition and competition designs there is, now-a-days, an affectation of powerful pictorial display, by means of meretricious colouring, exaggerated and unnatural shadows and tricky effects—amounting sometimes to downright falsification, cannot be denied, and is likewise to be deprecated as an abuse, because it imposes on the eye, and draws away the judgment from a sober examination of the design itself. Yet while we deprecate the abuse, we are not quite disposed to go along with Mr. Gwilt into the other extreme, and forbid not colouring alone, but shadowing also. Very far, indeed, too, are we from being of opinion that architectural drawing has deteriorated since the time of Jones, Wren, and Vanbrugh; for we should as soon think of saying that architectural engraving has declined since the days of Holler. That Mr. Gwilt is perfectly sincere in what he says, cannot for a moment be doubted; for, though he may be aware that they are not likely to be very popular, he utters his sentiments not only without disguise, but in a tone sufficiently emphatic; for instance, —"the greatest curse that in these days has fallen on architecture, is the employment of draughtsmen, who, with their trumpery colouring and violent effects, mislead the silly men and common-place critics that usually decide upon the merits of their works." This is severe enough, nor is it entirely free from prejudice—a little overcharged, perhaps, both in opinion and expression, therefore Mr. Gwilt must not be very much surprised if some should attempt to retaliate, and charge him with making use of very coarse language; be that as it may, we ourselves do not like his work the less for its occasional pungency of expression, which, even when we dissent from the sentiment, is more to our taste than the smirking, wishy-washy style of many other writers.

The more practical part of the work contains a great deal of information—of course not entirely fresh, and therefore more or less familiar to professional men; but it renders this Encyclopædia a complete elementary course for the student, affording him, in a single volume, the instruction that he must else gather for himself from a variety of publications. Still, it is questionable whether it would not have been more advisable to publish some of the sections separately, in the form of a supplement to be bound up with the rest by those who choose to take it, because so much matter of that kind, incorporated as it now is in the volume, may deter not a few from becoming purchasers.

(To be continued.)

perhaps, because their opinion of it is no better than Mr. Gwilt's—we shall probably take up the subject ourselves.

[2] The omission of such names is all the more extraordinary, because that of Brettingham is inserted, notwithstanding the discredit attached to it even by Mr. G. himself, who remarks that he had the unparalleled assurance to send out to the world as his own, Kent's Designs for the Earl of Leicester's seat at Holkham—a contemptible and dirty trick, but not an unparalleled one in the history of architectural publications.

[3] Since shops there must be, the very least that can now be done is to take care that they shall be as little obtrusive in appearance as possible, to which end prohibitory clauses ought to be introduced into the leases, forbidding not only show-boards, but all display of articles at the windows, where only blinds should be allowed, with the names and business of the respective tenants painted on them. This could not be complained of, because the restrictions would be imposed alike upon every one, and no one is compelled to become a tenant if he should object to the conditions.

Ancient and Modern Architecture. Edited by M. JULES GAILHABAUD. London: Firmin Didot, and Co. Part 3.

Another part of this excellent work has appeared, which is fully equal in interest to the former numbers; it contains a rich specimen of the Lombard style, the Carthusian Church near Pavia, Italy: the façade is covered with most elaborate ornament, which is shown in detail in another plate. The third plate is a view of the Cathedral of Bonn, in Germany, a fine specimen of the Norman style; the principal elements, however, present in general, the characteristics of the modified Byzantine style, but not so pure as that style. The eastern apsis, with its two towers, seem to belong to the close of the eleventh century or the beginning of the twelfth. This edifice contains some excellent points, from which the architect may glean with advantage, and turn to good account for some of our new churches. We know of no work that will add so much to the taste of the architect as the one before us.

Turning and Mechanical Manipulation. By CHARLES HOLTZAPFFEL, A. Inst. C. E. Vol. 1. London: Holtzapffel & Co., 1843.

We have been able only to give a cursory glance at this work, but from what we have seen, we have no hesitation in pronouncing it to be a work of the highest use, both to the practical man and the amateur. Next month we shall return to it.

SEWERS OF THE METROPOLIS.

WE are heartily glad that some agitation has taken place on this subject, having been introduced by the Poor Law Commissioners. We are sorry that we cannot insert Mr. Donaldson's defence, as chairman of the Westminster Commissioners, but we hope to advert to it next month; for although we do not agree with Mr. Chadwick in many points, we strongly hold that the present system of sewer administration is susceptible of improvement, so as greatly to relieve the proprietor and builder, and induce parties to construct sewers who now shrink from such a responsibility.

NOTES OF THE MONTH.

The new Law Courts in Guildhall-yard are to be immediately erected from the designs of Mr. Tite, F. R. S. The elevation next to Guildhall-yard is to be in the Gothic style, and the buildings on the opposite side, now occupied as the Guildhall Police Office, &c., are, it is said, to be re-fronted, to correspond in appearance. Guildhall Chapel formerly occupied the site of the Law Courts, and the style of that edifice might well be used in the present design; at the same time we sincerely hope that the style of Guildhall front will not be adopted, but that the present opportunity will be taken advantage of to get rid of the cocked-hats and other barbarisms which Master Dance was pleased to call Gothic, and which we should call *Gothic par excellence!* Several of the Common Council have advocated such a course, and we hope will persevere.

The ground for the new Conservative Club, in St. James-street is cleared of the buildings upon it, and shows a frontage of 150 feet. The building, it is expected, will be commenced in the ensuing spring, from the joint design of Mr. Sydney Smirke and Mr. Basevi.

The restoration of Wells Cathedral has been entrusted by the Dean and Chapter to Mr. Cockerell, R. A., and it is at present to be confined to the choir and organ.

The Temple Church is fast approaching completion. The floor is being covered with inlaid tiles, manufactured by Messrs. Minton, of Staffordshire. Next month we hope to be able to give some account of the restorations.

The Lycian marbles discovered at Xanthus by Mr. Fellowes have arrived at the British Museum, and their public exhibition is awaited with much anxiety on account of the merit they possess. We have before expressed our opinion that much of value connected with Persian art remains to be discovered, and recent discoveries in the East tend to confirm this. The remains of Persian art which have as yet reached Europe, show a promise of something better than we have yet had, and illustrate the influence of Persia on Greek art, of which abundant evidence is shown in the Lycian marbles.

On the Travellers' Club a new attic is being raised, so as to relieve the garden-front now swamped by the Reform Club and Athenæum. The addition is in the same chaste style as the rest of the building. The only part which is looked upon with doubt is the inhersion of telescopic circular windows in the roof. The interior is to be decorated by Sang, a German artist, with arabesques, and used as a smoking-room. In reference to Barry's application of colour we have heard some remarks upon the decoration of the groined arcade at the Travellers' Club. This he has had painted in imitation of granite, thus appearing to violate probability, as it would be difficult to work granite in such a way.

The Noah's Ark on the top of the Mansion House has at last been removed, to the great satisfaction of the public.

Cateaton-street is rapidly advancing, and will make a fine street. Guildhall is, as we have announced, to be improved. St. Lawrence Jewry and Gresham Hall abut upon the street. The latter building is to have a highly decorated front, in the florid Italian style, of four Corinthian pilasters. It is by far too small for the purposes to which it is to be devoted.

The widening of Fetter-lane, at the Fleet-street end, is determined upon, and the houses have been removed.

Mr. Barry's works in Trafalgar-square now begin to show themselves. The shaft of Mr. Railton's Nelson column is nearly completed, and the bronze capital which is being cast at Woolwich is in an advanced state.

A new Hall and Library are to be built in Lincoln's-inn, from the designs of Mr. Hardwicke, and are, we understand, to be in the style of the old parts of Hampton Court.

We have seen a line engraving of Barry, by Hurland, which is in private circulation; it is 8 inches by 6½ inches, and beautifully executed, but we do not consider it a striking likeness.

METROPOLITAN IMPROVEMENTS.

Whitehall, November 30th.—The Queen has been pleased to appoint the Earl of Lincoln, Lord Lyttleton, Lord Colborne, the Right Hon. James Charles Herries, the Right Hon. the Lord Mayor of the city of London, Sir Robert Harry Inglis, Bart., Sir Charles Lemon, Bart., Henry Thomas Hope, Esq., Henry Gally Knight, Esq., Alexander Milne, Esq., the Hon. Charles Gore, Sir Robert Smirke, Knt., and Charles Barry, Esq., to be Her Majesty's Commissioners for inquiring into and considering the most effectual means of improving the metropolis, and of providing increased facilities of communication within the same. The Queen has also been pleased to appoint Trenham Walshman Philipps, Esq., to be Secretary to the said Commission.

IRON STEAM VESSELS.

Sir—The writer of a paper on steam navigation in the November number of the *Journal* says, "The iron of which vessels are composed has been found to become brittle in the course of years, so that, although tough at first, it will, in the course of time, star like glass, when struck by a hard and sharp body." May I be allowed to remark that some of the friends of iron ship-building are startled by the assertion contained in this sentence, and would be glad to know whether the author of it can point to any instance of such "starring" which has actually taken place. Until this can be done, the examples of the *Aaron Manby*, which is stated in the same number of the *Journal* to have been at work from 1822 to 1830, without requiring any repairs, although she had been *repeatedly aground* in the Seine, *with her cargo on board*, and which vessel is also stated to be *now* at work,—of the steamer built by the Horseley Company for the Shannon, in 1825, and now "in good order," and of other iron vessels, do not appear to favour very strongly the serious objection raised against iron vessels in the paper quoted above.

I am, respectfully,

Neath, 12th mo. 10th, 1842. A. M.

[The objection alluded to by our correspondent is very well known to exist, by those whose acquaintance with the working of iron steam vessels is the most extended. In the *Lady Lansdown* iron steamer on the Shannon, the effect of a collision when the vessel was new was merely to indent the plate; after the vessel had been at work for some time, a tendency was observed in the plate to crack, as well as to become indented, and the brittleness of the plate was found to increase as the vessel became older, until, when struck by a hard and sharp body, it starred in the manner we formerly stated. Whether this effect is due to the action of the water or to the tremor occasioned by the engine, we do not pretend to determine; if the latter, steam vessels of moderate power may undergo a less rapid deterioration, and something of the superior durability of the *Aaron Manby* may possibly be owing to the smallness of that vessel's power.—Ed.]

MEDHURST'S WATER VALVE.

Sir—Excuse my troubling you with the following remarks:—

I have been much surprised by repeatedly seeing reference made to a water valve invented by Mr. Medhurst, and particularly a description of it by Mr. Vignoles in his lecture in Cornwall, reported lately in the *Railway Times*, where he remarks that it is a very ingenious contrivance, the only objection being that the country the railway passes through must be perfectly level—a serious objection certainly, but not the only one; for the learned Professor surely cannot be so unacquainted with the principle of the common pump as not to know that when the tube is exhausted of air, the water will rush in to supply its place, and so render the tube ineffectual. Another objection is that the communication between the piston and carriage being on one side only, the pipe must necessarily be on one side also—a very unmechanical contrivance, to say the best of it. The chances of the water freezing, or rusting of the piston, are left quite out of the question.

A Young Mechanic.

CONTRIVANCE FOR DESTROYING SMOKE.

Sir—At a meeting held at the Leeds Music Hall about ten months ago, I had the pleasure of examining a variety of models and drawings of patented smoke-consuming apparatus; also of hearing the same explained by the inventors thereof, or by their representatives. Previous to this meeting, I had paid little or no attention to "smoke burning," as it is commonly termed, but since, I have done quite to the contrary; I have been continually on the listen, and in full expectation to see from an individual, whose signature has occasionally appeared in your pages, a contrivance to effect the object in question more agreeable to my fancy than any I had seen. My expectation in this respect not being realised, and perceiving from a printed notice received from the Leeds Board of Works, about three weeks ago, that the period is fast approaching when all the "wholesale smoke manufacturers" within the borough of Leeds will, by Act of Parliament, be compelled to check, to a great extent, that nuisance which has been so long complained of, I began to think it high time to do something by way of experiment to diminish the periodical dense volume which rolled from my own chimney-top.

During the last three or four months, I have had frequent opportunities of witnessing the operation of several different kinds of apparatus for consuming smoke, some of them patented and some not; the whole of which I found wanting some improvement to render them capable of accomplishing their intended purpose still more effectually. This circumstance caused me to try a plan of my own, the success of which has induced me to hand you the present communication. After all the discussion and bother that has of late been *driven* up and down the country concerning the consumption of smoke, "smoke burning" is, nevertheless, in my humble opinion, as far as Englishmen have been enabled to succeed in the *science*, attended with so little difficulty as to be accomplished with very little trouble and expense. My furnace was recently one of the ordinary description, though it is now entitled to the name of a "smoke-burner," and the difference of the state in which it now is, and that which it formerly was, is simply this.

Cold air being admitted through a regulating door or valve built in the wall on one side of the ash pit, into a space or chamber formed within the wall which supports the fire-bridge, ascends through a narrow aperture extending across the top of the bridge, that is from one side of the boiler to the other into the flue, where it mingles, with the smoke, and thus renders combustion more complete. The air thus admitted into the flue can have no good effect any longer than it assists combustion; for this reason, if the engine man be a little attentive, he will generally find that the air valve may be shut in about four minutes after each renewal of the fire.

There are many "smoke burners" now in constant operation in this neighbourhood, some few of them appear to answer tolerably well, while others, *of the very same plan*, appear to have no effect whatever. This circumstance renders it impossible for a stranger to distinguish the chimneys which have "smoke burners" attached to them, from those which have not. I do not mean to say the plan I here describe is a perfect remedy for preventing the smoke of chimneys; it is such as I am convinced will protect me against any interference of the Leeds improvement commissioners; it has a better effect in accomplishing its object than a great majority of those in the neighbourhood; and it is inferior to none I have yet witnessed, except in one point, and that is of all others the most important, viz. *expence*.

From your humble servant,

Near Leeds, Nov. 29, 1842. FLEECE.

[We did not think it necessary to give the drawing forwarded by our correspondent, as we consider that the description will be sufficiently understood without it; this "smoke burner" is, we believe, identically the same as one that was patented some years since, which patent has expired.—ED.]

BLAST ENGINES.

SIR—I shall feel obliged by an explanation from you or from some of your correspondents in an early number of your valuable *Journal*, of the following irregularity of *blast* from a blast engine.

The engine blows four furnaces, three on one side, and one on the other side. There are two receivers, one exactly opposite to the gable of the engine house, into which the air is first forced, and another situated nearly equidistant from the three furnaces on one side of the engine. The blast to the three furnaces is taken from the bottom of the receiver at the engine house, and to the other furnaces, within a short space of the top, and about one foot above the orifice through which the blast passes from the engine to the receiver. I applied a mercurial gauge to various parts of the pipe leading to the single furnace, and I found the pressure varying irregularly from a quarter to three and a half pounds on the square inch; whereas the pressure on the pipes leading to the three furnaces kept uniformly three and a half pounds.

I am, Sir,
Your most obedient servant,

Clyde Iron Works, Glasgow, December 27, 1842. WILLIAM FERRIE.

ON THE STRENGTH OF BEAMS.

SIR—The above sketch shows the situation of the supports, &c., of a cast iron beam I lately had an occasion to make use of for carrying a load of about seven tons at each end. The distance between the supports *s*, *s*, was six times as great as that between the centre of each load, W, and the nearest support.

Now, I should feel myself highly obliged if some of your scientific readers would be kind enough to furnish the *Journal* with a correct method of shaping beams of this class; also the best formula for computing their strength. To prove where a beam of this kind would break, I took a parallel square bar of cast iron, divided its length, and placed it upon two supports, as seen in the sketch, then

submitted it to a pressure, acting equally upon the points, W, W, till it broke in the points *c*, *c*. Was I not to infer from this circumstance, that beams of the present kind require to be made strongest between the points of support? Query—Would this inference be consistent with theory? I don't remember seeing in any author on the subject, any satisfactory information relating to this class of bearers; still it is a form which in general practice is often found very convenient: and I have no doubt that if some of your able correspondents would give the subject a thorough investigation, the result thereof would be generally received as being of great practical importance.

Leeds, Dec. 17, 1842. CONCRETE.

OBSTRUCTIONS TO WINDOWS.

SIR—I have repeatedly endeavoured to obtain definite information on the subject of obstructions to windows (which have acquired a right by being opened upon adjoining property the requisite length of time) but having been unable to obtain any thing to be relied on, perhaps you, or some of your numerous and well informed correspondents can afford light on the following subjects.

1. Suppose a window to be opened upon an adjoining property, and (by neglect of the owner of such adjoining property) to acquire a right to remain open. What space of ground is required to be left open for its use, say in a direct line from its face, or the face of the wall in which it is built or opened?

2. Does the opening such window (of course it being possessed of the right as above) give any right to space on each side, or more than its own width.

3. Does it preclude the building of any structure beneath it, or as high as its sill.

These queries, you will perceive, are intended to cover all the ground of right of occupancy inherent in windows, which have been allowed to remain open a length of time sufficient to give what is termed a right of light.

By replying to the above, or giving it a place in your valuable journal,

You will oblige,

West Derby, Dec. 5, 1842. AN OLD SUBSCRIBER.

[We rather suspect that our correspondent will find some difficulty in obtaining a satisfactory answer to his queries, 1 and 2; we believe that there has not been any defined distance settled. At a trial, much depends upon the hard swearing of witnesses on both sides, as to whether a building erected near a window does obstruct the light and free circulation of air. After hearing of evidence, it is left to the Judge and Jury who may try the cause to determine the point. In answer to the third query, there is no doubt that the owner of the soil has a right to build beneath the window or as high as the sill; if in London, the roof must be 18 inches below or from the opening, to conform to the building act.—ED.]

SMITH'S PATENT WIRE ROPE.

AT the Society of Arts, on Wednesday, the 11th December, a paper by Mr. A. Smith was read, "*On the properties of Wire, as applied in the Manufacture of Rope for Mining and Railway Purposes, Standing Rigging, Lightning Conductors, Cables, &c.*" After some preliminary remarks on the increment of strength, as compared with diminution of bulk, resulting from the processes of drawing and annealing the wire, Mr. Smith gave a table of the strength of single wires of various gauges, the breaking weights having been obtained by experiment with the testing machine. This was followed by a table of tests of the comparative strengths of the Government hempen-rope, and Mr. Smith's wire-rope, from experiments ordered by the Admiralty in March, 1837. Another table gave the comparative size, with the weight, and cost per fathom, of iron-wire rope, hempen-rope, and chain of equal strength. The general results are, that standing rigging of wire-rope, of equal strength with the hempen-rope, one-third of the size and half the weight, may be fitted at about two-thirds of the cost.

In the nautical statistics of Mr. Smith's paper it is stated, in reference to the advantages of a reduced surface of rigging, that "the standing rigging now fitted in her Majesty's navy, presents a surface of upwards of 800,000 square feet, which is about equal to the surface of the sails of twenty-four first-class frigates;" and in reference to the disadvantages of the absorption of moisture by the hempen-rope, that "one fathom of hempen-rope, about three inches in circumference, will absorb half a pound weight of water, and will contract one inch in length. The standing and running rigging of a first-rate measures about 30,000 fathoms, and will, consequently when wet, contract in length, on an average, about 880 yards, or nearly half a mile, and will absorb about seven tons of water, which, being principally carried aloft, will materially affect her sailing," &c.

Mr. Smith explained the construction of an apparatus termed a "screw lanyard," which he substitutes for the ordinary lanyards and dead-eyes of the shrouds, for the purpose of tightening the wire-rope rigging. It consists of a piece of Russell's wrought-iron tubing, with a screw at each end, working in right and left screw sockets.

The ship's lightning conductor is described as a copper-wire rope, securely fitted to the trucks and mast-head caps, and descending from the top-gallant and top-masts down the rigging, and over the ship's side, where it is inserted in a copper-plate, in contact with the sheathing below the water-line, &c.

On Wednesday, the 21st of December, Mr. Smith continued his communication. He commenced by explaining the tenacity and elasticity of various metals, and experimented by a testing machine on wires of platina, gold, silver, copper, and iron. He first tried a piece of platina wire, twelve inches in length, $\frac{1}{16}$ inch in diameter, and weighing 8 dwts. 5 grs; this experiment, however, failed from an accident. The gold wire, of the same length and size, (weight 5 dwts. 10 grs.) broke at 384 lbs.; silver, same size and length (weight 4 dwts. 14 grs.), broke at 260 lbs; copper, (3 dwts. 12 grs.) broke at 180 lbs.; and iron, 3 dwts., at 310 lbs. A copper rod, one-fourth of an inch in diameter, was then tested, which withstood a tenison of 2,000 lbs.; and an iron one, of the same diameter, did not break until a power was applied equal to upwards of 3,000 lbs. A wire bridge, of 33 feet span, was erected in the room, the construction of which Mr. Smith explained. The wire rope, forming its principal support, weighed 56 lbs.; the angle-irons, 112 lbs.; and the other parts, including the braces, 56 lbs.; and 112 lbs. for the platform or footpath, composed of boards —thus making the whole weight only three cwt., and which might be completed by four men, in about three days, at a cost not exceeding 15*l.*, and could, at any time, be taken down or put up in half an hour. These descriptions of bridges were described as very useful for military purposes, and for throwing over deep cuttings in railways, &c., Mr. Smith stated, that for general practical purposes the cost might be taken at 1*l.* per foot run, with a breadth of three feet. Two smaller models of bridges, on different principles of construction, were also shown.

KEENE'S MARBLE CEMENT.

At the Society of Arts a paper was lately read by Mr. White, "*On Keene's Marble Cement.*" It is described as a combination of sulphate of lime and alum. The gypsum undergoes the same preparation as for plaster of Paris, being deprived of its water of crystallisation by baking. It is then steeped in a saturated solution of alum, and this compound, when recalcined and reduced to a powder, is in a fit state for use. The cement has been extensively applied as a stucco, but the finer qualities (when coloured by the simple process of fusing mineral colours in the water with which the cement powder is finally mixed for working) being susceptible of a high degree of polish, produce beautiful imitations of mosaic, and other inlaid marbles, scagliola, &c. The cement is not adapted to hydraulic purposes, or for exposure to the weather, but has been used as a stucco in the internal decorations of Windsor and Buckingham Palaces. From its extreme hardness, it has been found serviceable when used for imbedding and setting the tiles of tesselated pavements, &c., and has been adopted for this purpose at the French Protestant Church, the new fire-proof chambers in Shorter's-court, and the Reform Club House. In the course of the discussion which followed, Mr. C. H. Smith and Mr. Lee adverted to the extreme hardness of the cement as its principal recommendation, when applied as stucco and for mouldings.

[We have seen some of the imitations of mosaic and inlaid marbles referred to in the above paper; we can say, and truly, that they are beautiful, and in point of polish superior to scagliola; we have also seen some fine specimens of granite, imitations in plinths for halls, chimney-pieces, columns, pilasters, &c.; and we must not forget to mention the imitation statuary mouldings, with polychrome ornaments, after the Greek. For the purposes of interior ornament, we consider this cement a great acquisition to the architect. We, therefore, strongly recommend the profession to visit Messrs. White's works, where may be seen various applications of the cement for decorative architecture, particularly two table tops, containing several imitations of rare marbles.]

THE SILLOMETER, DERIVOMETER, SUB-MARINE THERMOMETER, AND STEAM-ENGINE INDICATOR, OF M. CLEMENT.

At the request of a subscriber to give some information relative to M. Clement's Nautical instruments, for which Government lately made a grant, we make the following extracts from the *Mechanics' Magazine*:—

1. The *Sillometer* is the title given to a substitute for the common log, which has been recently invented by a M. Clement, of Rochfort, and is so well thought of by the French Admiralty, that it has been ordered to be forthwith supplied to the different ships of the Royal Navy of France. It is a most ingeniously constructed instrument, and promises to be of great practical utility. To describe it as well as we can in words:—

A hollow copper ball, against which the water acts, is attached to a moveable plug of the same metal, which slides in a copper tube that passes through the centre of the vessel to the keel; to this plug is attached a lever, which, by means of a vertical rod, acts on a second lever placed on the deck of the vessel, and communicating with a spring; the tension of the spring constitutes an equilibrium with the pressure of the water on the ball, and serves to measure the rate at which the ship is moving, by means of a hand, the movements of which on a graduated dial, indicate, at every movement, not only the speed of the ship, but also the distance run in any given time.

2. The second invention is called a *Derivometer;* it is an instrument to ascertain a ship's leeway, and is moved by a paddle, that may be placed under the keel at will, and is supported by a plug sliding in a tube like that of the Sillometer, but turning with the paddle and the rod. The motion is transmitted from the paddle and rod to two semi-circular dials, one of which indicates the leeway to larboard, the other to starboard. When at anchor, the instrument will show clearly the direction of the currents.

3. The third invention is a Sub-marine Thermometer. It appears from the thermometrical observations of many scientific navigators, that in seas of unfathomable depth, the water is not so cold as over banks, and that over banks near the shore it is less cold than over those at a greater distance, but colder than in the open sea. M. Clement's thermometer is kept constantly under water at the same depth, and indicates the different temperatures of the water by means of a dial placed on the deck of the vessel, and always open to examination. The immediate action is communicated by wheels, the working of which turns two hands upon the dial, the one marking the single degrees, and the other the tens. The whole is enclosed in a tube attached to the side of the vessel, and the helix of the apparatus is at the lowest part of the tube, in immediate contact with the water, and always at the same height.

4. The fourth invention consists of an instrument which indicates constantly the elasticity of the steam both in high and low-pressure engines, and the level also of the water in the boilers. The instrument may also be applied to the piston of an engine, so as to show the loss of power sustained by the steam in its way to it. A tube, similar to the manometer, is affixed to the instrument through which the steam ascends, and is introduced into a copper or brass box placed on the deck of the vessel, and upon which a graduated dial indicates, by means of a hand, to the officer of the watch, the effects of the engine, without his having to send below to ascertain it.

M. Clement has obtained patents for these different inventions both in France and this country.

The following experiments made by order of the Lords of the Admiralty on board of the *Lightning* steamer, we extract from the Government report.

"*Thursday, October* 13, 1842.

"About one mile and a quarter below Gravesend commenced a trial between Massey's patent log and M. Clement's sillometer. After a run of two hours and a half (being off Sheerness)—

	Miles.
"Distance given by Massey's log . . .	$15\frac{1}{10}$
"Distance given by sillometer . . .	15
"Distance from the Nore Light to Deal by sillometer	42
"Distance by tables	$41\frac{3}{4}$

"At 25 minutes past 4 o'clock, P.M., altered the course four points, during which operation the sillometer showed a diminution of speed from 8 miles per hour to 7 miles. At 50 minutes past 8 o'clock P.M., off South Foreland, commenced a trial between Massey's log and the sillometer.

"On Friday morning took in Massey's log, and found the distance from abreast the South Foreland to about 7 miles to the eastward of the Owers—

by Massey's log $84\frac{3}{4}$ miles; by sillometer $82\frac{1}{2}$; by tables 85 miles. Moved sundry weights aft, viz., boat, brass guns, anchors, oars, &c.: for an instant the speed, as shown by the sillometer, diminished to 7·4 miles per hour, but it almost immediately increased to the former speed of 8 miles per hour. Moved the same weights forward, but could not perceive any sensible difference in the speed of the vessel. The speed, as shown by the sillometer, varied from 8·1 to 8·2 miles per hour. Tried the speed of the vessel by the common log, which gave $8\frac{1}{4}$ miles. The sillometer indicated exactly the same. At 10 o'clock, A.M., on Friday, when about two miles past the Nab Light, tried Massey's log, and found the distance to near the entrance of Portsmouth harbour—by Massey's log six miles nearly; by sillometer six miles exactly. During the passage round to Portsmouth, the speed of the vessel was purposely checked, by blowing off the steam, to see the effect on the sillometer. The speed, as shown by that instrument, was gradually reduced from eight miles per hour to four miles, at which point it stood steady. On the order being given for full speed, the sillometer showed a gradual increase of speed, till it came to 8 miles per hour, as before. On the return of the *Lightning* from Portsmouth to Woolwich, the distance performed was found to be—by Massey's log 119 miles; by the sillometer 118·6.

"The sillometer has a dial upon deck, which constantly shows the number of miles per hour that the vessel is going; consequently it is easy to discover, under all circumstances, what is the best trim of the vessel, and the most advantageous quantity and distribution of the sails for obtaining the greatest speed. As the sillometer shows immediately the effect which every alteration in the sails or trim of the ship has on its velocity, it follows, also, that ships fitted with the sillometer can constantly maintain the speed they may have agreed upon, and so keep company together, and maintain the same relative position, though, from the darkness of the night, or thickness of the weather, they cannot see each other. To ascertain the distance run after any number of hours, it is simply to take the number of minutes one of the watches of the sillometer has gained over the other, and to multiply that number by six, which gives the distance run in miles.

"*The Marine Thermometer.*—The trials with this instrument on board the *Lightning*, commenced at 11 o'clock on Thursday morning, October 13, previous to leaving Woolwich harbour, and on taking the centigrade, it was found to be 12°. At 25 minutes past three o'clock P.M., in five fathom channel, cant-shoal, depth of water about 16 feet, it indicated 13·25°. In 23 feet depth of water, as stated by the pilot, it indicated 15·25°; off Dover 16°; and in Portsmouth harbour, 14·2. From these indications it appears that the marine thermometer in its variations followed the inequalities of the bottom of the sea, so far as these inequalities could be ascertained from the heaving of the lead, or from the information of the pilot—that is, on the aproach of shoal water the thermometer fell, and on the approach of deep water it rose, and distinguished the difference very distinctly and rapidly, according to the transition from shallow to deep water, and *vice versâ*. It may, therefore, be inferred that the marine thermometer would indicate the approach to rocks and icebergs, from the influence these bodies are known to have on the temperature of the sea for a considerable distance." The dial of the marine thermometer is also on deck, and shows, by inspection merely, the exact depth of water in which the vessel may be sailing at the time.

Sunderland Harbour Floating Dock.—Application is intended to be made in the ensuing Parliament for an act to authorise the Wear Commissioners to convert the lower part of the Tidal Harbour of Sunderland into a Floating Dock, by a course of dams, piers of masonry, with navigable gates between, across the River Wear. The works are intended to confine or impound seven feet of water above the low water-mark of the average spring tides in this part of the harbour; 100 acres of water will thus be rendered available to shipping, producing at Pallion a depth of five feet in the Channel, and at the Folly End an average depth of 12 feet. Facilities for moving ships in and out of loading berths, and increased accommodation for ships of a larger class, will thus be secured. The navigable gates to be each 80 feet in width of opening, with sluices or slackers in them for letting off the water when required. These gates are proposed to be left open till three hours after high water, or until the water has ebbed out to the height above specified. Ample time will, therefore, be given for ships passing outwards. The gates are to remain closed until the tide has again flowed to the level of the confined water, of three hours flood, when the tidal water will force them open, and the navigation of the stream will again proceed as at present. It is also proposed to construct a Tidal Dock or Basin, to contain 25 sail of vessels, for the purpose of having an entrance to the great Dock always available. Mr. Murray, the Commissioner's engineer, has prepared the necessary plans for the intended works. The Parliamentary plans have been lodged.

The New Barracks at Preston.—We understand that the plans and specifications for the new barracks at Fulwood, near Preston, have at length passed, and received the confirmation of the Hon. Board of Ordnance. They will be on the most magnificent and complete scale, superior to any in the kingdom, to accommodate 2,000 men, with stabling for 750 horses.—*Preston Chronicle.*

INSTITUTION OF CIVIL ENGINEERS.

The Council of the Institution of Civil Engineers have awarded the following Telford and Walker Premiums for 1842.

Robert Thomas Atkinson, M. Inst. C. E., for his Paper "On the sinking and tubbing, or coffering of Pits, as practised in the Coal Districts of the North of England," a Telford Medal in Silver, and Books.

William Cotton, for his "Memoir of Captain Huddart," a Telford Medal in Silver.

Chevalier Frederik Willem Conrad, for his "History of the Canal of Katwyk, (Holland,) with an Account of the Principal Works upon it," a Telford Medal in Silver.

James John Wilkinson, for his "Historical Account of the various kinds of Sheathing for Vessels," a Telford Medal in Silver.

Thomas Casebourne, M. Inst. C. E., for his "Description and Drawings of part of the Works of the Ulster Canal," a Telford Premium of Books.

Thomas Girdwood Hardie, Assoc. Inst. C. E., for his "Description and Drawings of an Iron Work in South Wales," a Telford Premium of Books.

Charles Nixon, Assoc. Inst. C. E., for his "Description and Drawings of part of the Tunnels on the Great Western Railway," a Walker Premium of Books.

Alexander James Adie, for his "Descriptions and Drawings of the Bridges on the Preston and Bolton Railway," a Walker Premium of Books.

John Brannis Birch, Grad. Inst. C. E., for his "Description and Drawings of the Bridge at Kingston-on-Thames," a Walker Premium of Books.

Robert Richardson, Grad. Inst. C. E., for his "Description and Drawings of part of the Works of the London Docks," a Walker Premium of Books.

James Combe, Assoc. Inst. C. E. for his "Description and Drawings of Messrs. Marshall's new Flax Mill, at Leeds," a Walker Premium of Books.

Charles Denroche, Grad. Inst. C. E., for his "Description and Drawings of the Apparatus used for Compressing Gas, for the purposes of Illumination, &c.," a Walker Premium of Books.

Adrian Stephens, for his "Description of the Explosion of a Steam Boiler at the Penydarran Iron Works, South Wales," a Walker Premium of Books.

George Ellis, Grad. Inst. C. E., for the Drawings illustrating the "Description, Specification, and Estimates of the Calder Viaduct, on the Wishaw and Coltness Railway; with the Series of Experiments on the deflection of Trussed Timber Beams for that work, by John Macneill, M. Inst. C. E.," a Walker Premium of Books.

Thomas Chalmers, Grad. Inst. C. E., for the Drawings illustrating the "Report on the Sinking of two experimental Brick Cylinders, in an attempt to form a Tunnel across the River Thames, by John Isaac Hawkins, M. Inst. C. E." a Walker Premium of Books.

THE NILE.

The following account of the plans adopted by Mehemet Ali for carrying into execution the improvements of the Nile, first conceived by the Emperor Napoleon, is transmitted to Paris by Dr. Labot, who arrived lately in Egypt. The first great work is to be the establishment of a bridge of 83 arches, running from the point of the Delta to each of the opposite banks of both branches, similar to the Pont-Neuf at Paris. On each side of the spur, a sluice is to be formed for the purpose of Navigation. All the 83 arches are also to be furnished with flood-gates of iron or wood, to be opened or shut according to the wants of traffic and navigation. A tunnel is to be cut through the spur of the Delta, forming a communication between the two branches of the river. Canals are also to be cut from each branch running to the east and the west, with various minor channels, with sluices for the commerce and irrigation of the country. Above the bridge, the Nile is to be embanked on each side, so as to keep the water always within a certain level. All these embankments will be faced with masonry to give to them solidity and beauty. Concrete will be used for all the submarine works, and the rest will be done with squared stone, rubble, and bricks. These materials are found in abundance in Egypt, and even in the immediate neighbourhood of the works. Artificial pozzolano is in general use, being obtainable in all parts of the country from pulverised bricks. This matter, which is analogous to that produced by volcanos, being mixed with lime and rubble, form what is called beton or concrete. Before the discovery of this pozzolano, which costs 5 fr. the cubic metre on the spot, it was formerly brought from Italy, at the expense of 45 fr. or 50 fr. the cubic metre. The cost of the bridge has been estimated at 7,000,000 fr., and cannot exceed 10,000,000 fr. When once the materials are collected, it will require no more than three years for 5000 men to complete this colossal undertaking which will vie in grandeur with the celebrated monuments of ancient Egypt. According to a calculation recently made by a Parisian engineer, it appears that the present irrigation of Egypt, though very limited in comparison to what will now be accomplished, costs the labour of 200,000 oxen and 100,000 men.

MISCELLANEA.

The Tomb of Napoleon.—The construction of the tomb of the Emperor Napoleon is about to be commenced, and for the last few days a model of the work has been exposed to public view at the Invalides. An equestrian statue of the Emperor is to be placed in the middle of the great court, and on the pedestal will be represented the arrival of his ashes at the place where they now lie. The entrance of the crypt destined to receive the Emperor's mortal remains will be ornamented on each side by two gigantic statues and two lions couchant. This entrance will be surmounted with an altar on spiral columns. The present grand altar and its rich canopy must be removed to admit of this arrangement.

The Tuileries and the Louvre.—The *Globe* notices a rumour, that during the next session of the Chambers the plan for uniting the palaces of the Tuileries and the Louvre by a screen, resembling in architecture the façade front of the Quay de Louvre, and thus forming one of the finest squares in Europe, will be presented. The centre will, it is said, according to this project, be ornamented with an equestrian statue of the Duke of Orleans, and the works are to be entrusted to the direction of the Civil List. The expense to be divided into thirds: one to be borne by the Civil List—one by the State—and the last by the city, to be laid out in embellishments. If this project be adopted, the idea of purchasing the site bounded by the Pont-Neuf, the Quais d'Horloge and des Orfevres, and the Rue du Harlay will be relinquished, and the new wing or screen of the Louvre will be appropriated to the Royal library.

The New Corn Exchange, Glasgow.—The spacious and beautiful hall which has been erected in Hope-street as a Corn Exchange, for the accommodation of those engaged in the grain trade, was opened on Wednesday 23rd November, for the first time, when the respective stalls were taken possession of by their tenants, and a good deal of business transacted. As this building, independent altogether of the important object it is destined to serve, is an ornament of a very high order to that part of the city in which it has been erected, we deem it worthy of a special notice. The exterior is finely relieved by a handsome range of Roman windows, and is decorated all round the spot with a massive balustrade, while the entrance which fronts Hope-street, is adorned with a beautiful portico, formed of Corinthian columns, 25 feet in height, finished with a corresponding entablature and pediment. The front has been designed in a style of great chasteness and purity, the work executed with much skill, and the entire building presents a noble and imposing appearance. The hall within is exceedingly spacious, and has a very striking aspect, being of a construction altogether different from that of any other building in the city. It is entirely lighted from cupolas tastefully introduced into the panels of the ceiling, and ornamented by a magnificent lantern light 50 feet by 30, formed in the centre of the building, and supported by eight columns, fluted, and ornamented in the Corinthian style. The dimensions of the hall are 80 feet by 57; the height of the ceiling 22 feet; and, viewed as a whole, it has an exceedingly light and elegant appearance. There have been erected round the hall 36 stalls for the grain merchants, so formed as to give facilities for exposing their samples, for writing, and otherwise carrying on business. They are let at the rate of 10*l.* each per annum, and we understand that 31 of them have already been taken, the name of each tenant being painted on his stall. Underneath the hall, which is reached by a short flight of stairs from the pavement, is a large grain store, perfectly capable of containing nearly 800 tons of grain. The building, so creditable to the parties chiefly connected with the grain trade, with whom it originated, has been built by subscription shares of 50*l.*; and the speculation bids fair for being a very profitable one. The architects are Messrs. Brown and Carrick, who, throughout the whole details, have manifested a degree of taste, skill, and ability, which cannot fail to add to their reputation.—*Glasgow Chronicle.*

Statue of the Queen at Edinburgh.—A colossal statue of Her Majesty Queen Victoria, is now being executed in freestone, by Mr. Steell, sculptor, and which is to be placed in the north front of the Royal Institution, Prince's-street. One stone is upwards of 22 tons weight: and was brought from the Binny Quarry to town on a wagon drawn by 16 powerful horses, assisted at certain difficult parts of the road by a number of Mr. Lhind's men. It was safely lodged in a large wooden building, Bread-street, where Mr. Steell is already far advanced in the formation of this gigantic structure, and which, when completed, will weigh altogether upwards of 90 tons. From the well known talents of the artist, the beauty and solidity of the Binny stone, and the commanding situation it is to occupy, this statue of our beloved Sovereign cannot fail to be an object of great attraction, and will complete the beauty of the splendid building it is intended to adorn.

Architectural Remains in Asia.—The *Commerce* states, that "most favourable news had been received from M. Tessier, appointed to direct the expedition sent to Magnesia, in Asia Minor, in order to raise the remains of the temple of Diana Leucophica. It appears that many more objects had been discovered than was originally expected, amongst others several columns in complete preservation, with their capitals sculptured with extreme delicacy, besides 12 bas-reliefs admirably executed, and a number of statues. The most friendly aid had been afforded by the French authorities in the Levant, and it is expected that a brilliant harvest is being reaped for the Academy des Beaux Arts at Paris."

The New Royal Exchange.—Notices have been given by the city authorities for pulling down the mass of building in front of the Bank (known as Bank-buildings) in the course of the spring, and the space, when cleared, is to be the site for the statue of the Duke of Wellington, immediately in front of the great portico of the Exchange. The progress made in the building itself is most astonishingly great, reflecting the highest credit upon Mr. Tite, the architect, and Mr. Jackson, the contractor. In the course of this year the work will be in great forwardness, and it will certainly be finished in the summer of the following year. The sculpture of the pediment Mr. Westmacot undertakes to complete by the 1st of May, 1844.

Timber Tank.—A wrought iron cylinder, 51 feet long and 6 feet diameter, has been erected in Portsmouth Dock Yard, for the purpose of "Burnettizing" timber under pressure. It is composed of plates half an inch thick, and double rivetted, and the ends are of cast iron, with doors 2 feet 6 inches square, for the admission of logs. It is fitted with two air pumps of 14 inches diameter, for extracting the air, and two force pumps for increasing the pressure when filled with the solution. On a trial lately made before the Admiralty engineer Mr. Kingston, the cylinder having been charged with 20 loads of timber, the air pumps which are arranged to be driven by Lord Dundonald's rotary engine, were set to work, and a vacuum of 26½ inches was obtained in 30 minutes. A cock in the connecting pipe was then opened, and the solution rushed into the vacuum from the cistern. When the cylinder was filled with the solution, the force pumps were set to work, and the pressure was raised to 200 lb. on the square inch. Under this pressure there was not the sligbest leakage from any part of the cylinder, nor from the doors. The timber was removed on the following day, and a log was cut up, when it was found that the solution had penetrated to the very centre, and completely saturated it. The pressure at which the apparatus is in future to be worked, is 100 lb. on the square inch, as this is found to be sufficient for the due saturation of the timber within 24 hours, under the process of previous exhaustion of the air. The whole of the work was executed by Messrs. W. Fairbairn and Co., of London, and the cylinder rivetted up by their patent rivetting machine, to which its great tightness may be attributed.

New Iron Steamer, "The Magician."—An iron vessel, of 360 tons burthen, built by Messrs. Ditchburn and Mair, with engines of 110 horse power, by Messrs. Penn and Son, and fitted with Morgan's patent wheels, tubular boilers, and Howard's cooling apparatus, was tried during last month, and has proved to be a first-rate steamer; in point of speed she is not to be excelled. The following account of experiments we extract from the Woolwich correspondent of the *Times*:—The experiments were made on the 16th, 17th, and 18th of November. The vessel left Woolwich about ten o'clock, a.m., on the 16th, and in about half an hour afterwards passed the *Rhadamanthus*, which had left Woolwich at nine o'clock. At about half-past 11 o'clock she stopped for a few minutes at Gravesend, and then proceeded with a strong breeze ahead, and adverse tide, and at a quarter past one o'clock passed the Nore-light vessel; arrived at Ramsgate at 25 minutes past four o'clock, when the weather was so severe, that none of the London steam-vessels arrived during the course of day. The weather continued so boisterous during the 17th, that the *Widgeon* steam-vessel was under the necessity of putting into Ramsgate harbour at an early hour for shelter. The *Magician*, however, left Ramsgate shortly after 11 o'clock, a.m., the wind blowing at the same time a strong breeze from the eastward, and at 53 minutes past 12 o'clock passed Dover Pier, with a very heavy sea running. At 24 minutes past one o'clock, when opposite Folkstone, she put back for Ramsgate, where she arrived at 44 minutes past three o'clock. On the 18th the *Magician* left Ramsgate at 17 minutes past ten o'clock, a.m., with flood tide, and at 14 minutes past three o'clock, p.m., arrived off Woolwich. The average speed of the engines from Ramsgate to Woolwich was 35¼ revolutions per minute, length of stroke three feet six inches, height of steam-gauge seven inches, height of barometer 28¾ inches. The boilers are constructed on the tubular principle, very small, and generate steam well. The consumption of coal was about 6lb. per horse-power per hour, and the vessel was found to be extremely easy and dry in a heavy sea. The average speed of the vessel from Ramsgate to Woolwich, the distance being estimated at 85 miles, in five hours, was equal to 14 knots, or 17 statute miles per hour.

Dover.—Few persons are perhaps aware that our harbour commissioners have determined upon making the most extensive alterations and improvements for widening and generally enlarging the harbour; so extensive, no doubt, as to leave it beyond a matter of question that the Government intend making Dover harbour one of refuge. All the "old buildings," including the Dover Castle Inn, Amherst Battery, and the warehouses and buildings occupied by Messrs. Gilbee, Norwood, Spice, Dennis, Clarke, and others, are to be pulled down, and their sites thrown into the harbour. The whole of Union street also is to come down, with the exception of Messrs. Latham's Bank and the York Hotel. The railway will clear away Beech-street, the whole of the South Pier houses, and a part of Seven-star-street, which will include nearly all the shipwrights in Dover, not even excepting Mr. Duke, whose residence will also come down. These changes must have an extraordinary effect on all the trades of Dover, who will speedily be called into action for the purpose of supplying the "houseless wanderers" with places wherein to hide their heads.—*Dover Telegraph.*

New Locomotive Engine—"The Man of Kent."—Messrs. Rennie have turned out another locomotive that promises to excel the "Satellite," sent out by the same firm about 12 months since, and which has been working on the Brighton Railway with so much satisfaction and economy, the average consumption of coke being not more than 20 lbs. per mile, with a train of eight or nine carriages. It lately performed the distance from Croydon to Brighton, 40½ miles, with six carriages, in 52 minutes, including three stoppages of three minutes each, which deducted, make the actual time running only 43 minutes. During the whole period of 12 months it has been running not one shilling has been laid out for repairs. "The Man of Kent" promises even to excel these excellent qualities of the "Satellite;" it is a splendid specimen of engineering work, and possesses several improvements; among others is an important one of encasing the cylinders, which are 15 inches diameter, with a jacket, which will always be kept charged with hot steam; a second improvement, is the introduction of a damper, so constructed, that the apertures of the tubes next the smoke-box may be wholly or partially eclipsed simply by the driver turning a handle, which regulates the draft of the engine to the greatest nicety; a third improvement is in the regulator, which is generally circular consequently difficult to keep tight—it is now a slide valve. The centre of gravity is kept down by the spring being below instead of above the axles, as usual. We hope next month to be able to give some account of its performance.

South Eastern Railway Works.—The stupendous works now proceeding for the formation of the South Eastern Railway between Dover and Folkstone are rapidly progressing, and extensive preparations are making to throw down a large portion of Rounddown cliff, just beyond the Shakespeare tunnel, to make way for the sea wall. During last month experiments were made by the miners below the cliffs, under the superintendence of Lieut. Hutchinson, and General Pasley is expected to be present at the grand operation; this blast is to be effected by the enormous charge of 18,000 lbs. of gunpowder; it will be exploded by the electric spark from a galvanic battery, carried by conductors 1,000 yards in length. The experiments have hitherto been quite satisfactory, and it is expected at once to dislodge a portion of the cliff many tens of thousands of tons in weight.

Comparative Cost of English and Foreign Railways.—In Mr. Robert Stephenson's elaborate and important report, addressed to the directors of the South Eastern Railway, on the system of railways, as now projected by the French government, he gives an analysis of the cost of railways in England, selecting three lines—the Northern and Eastern, the York and North Midland, and the Birmingham and Derby—as cases similar in their results to those in France now under consideration; from this, and also an analysis of the cost both of the Belgian and French lines, it appears the average cost per mile of the English lines is 25,450*l.*, the French lines, 23,000*l.*, and the Belgian lines, 16,206*l.*; thus showing a difference in the cost in favour of the Belgian lines over the English of no less a sum than 9,244*l.* per mile, and over the French of 6,794*l.*

Burning Lens worked by the Drummond or Oxy-Hydrogen Light.—A colossal burning lens, three feet in diameter, and weighing 5 cwt., has been erected in the Royal Adelaide Gallery, intended to be worked by the Drummond, or oxy-hydrogen light. Some private experiments of this power of the Drummond light have taken place, when it was found that the bulb of a differential thermometer introduced into the focus, at a distance of 16 ft., was sensibly affected, and a piece of phosphorus introduced in the same point was fused. It has long been asserted that the heat accompanying light obtained by artificial means does not produce heat capable of being transmitted and concentrated through lenses; these experiments fully prove the contrary.

Price of Gas.—Gas is manufactured in Manchester by the Commissioners of Police, and though sold at from 5*s.* to 6*s.* the 1,000 cubic feet, yields a revenue of 12,000*l.*, or 15,000*l.* per annum to the town. The large consumers pay 5*s.* the 1,000 feet. [In Dublin the charge, when burnt by meter, is 10*s.* the 1,000 feet, and the quality so inferior in illuminating power, as to require the holes in the burners to be about double the ordinary size. If our civic authorities would follow the example of the Manchester Commissioners, it might prevent the necessity for a burgh rate, and confer a boon on the gas consumers.]—*Dublin Advertiser.*

An Immense Block of Granite has been landed at Mr. Tuckvill's wharf, Greenwich; it is from the Haytor Company's quarries, Dartmoor; measuring 10 feet 6 inches square, and weighs 22 tons. It is to be used as a covering for a mausoleum in Kensal-green Cemetery.

Bell Rock Lighthouse.—During the late heavy gales which have done so much damage to shipping, particularly between the 19th and 23rd of October, the sea sprays appear, by the monthly returns from the Bell Rock Lighthouse, to have risen upon the building to the height of from 60 to 90 feet every tide. While this heavy sea ran, one of those great detached masses of stone familiar to the lightkeepers by the name of "Travellers" was forced across the rugged surface of the rock, about 100 yards to the lighthouse, where it destroyed part of the cast-iron landing wharf. This stone measured about 7 feet in length, 3½ feet in breadth, 2½ feet in thickness, and must have weighed about 4 tons. To prevent mischief by the movement of these great stones, the lightkeepers are provided with quarry tools, with which they broke it up and arrested its progress, but it was no easy task from the run of the sea. The heaviest seas which visit the Bell Rock are from the North-east, but the present gale was chiefly from the North west; and it is not a little remarkable that the Frith of Forth was but little affected during this storm above the Island of May.

Quarrying Stones.—Another remarkable example of the contributions of science to the arts of life is derived from the properties of heat as applied in the East to quarrying blocks of stone, when the object is to excavate huge blocks from the surrounding mass. A groove is cut some 2 inches in depth in the required direction; this done, the groove is filled with fuel, which is kept lighted until the rock is highly heated. The rock then is, of course, expanded by the action of the heat, the fuel is then swept away, and cold water immediately poured into the groove. The sudden contraction causes the block instantly to split off. The same principle is daily exhibited on our tables. If a heated glass be suddenly filled with cold water, it immediately breaks in pieces. In this way blocks 80 ft. long and 6 thick are easily taken off with no other labour than that of chiselling out the groove. A similar example of the application of science to the economy of power is exhibited in France in the quarrying of millstones. They are required, as you are well aware, to be circular and flat—cylinders with a very small altitude compared with the diameter—and the stone from which they are made is exceedingly hard. The mode of quarrying them is this:—A very high circular column of stone is wrought out of the requisite diameter. To slice off portions of this, such as are required by the common stone saw, would be a work of immense labour, a quite different agent is employed. At regular successive distances grooves are cut around the column, into which are driven dry wooden wedges at evening. The dew which falls during the night being absorbed by the wood, causes it to expand with a power so irresistible, that all the stones are found properly cracked off in the morning.—Dr. Lardner. *Lectures in the United States.*

Seyssel Asphalte.—Many of our readers may remember that some years ago, and previously to the introduction of asphalte into this country, we expressed our admiration of the pavement, composed of that substance in Paris, and especially of that in the Place de la Concorde, the whole of which has been long since paved with asphalte. It now behoves us to point out the piece of Seyssel asphalte laid down in April, 1838, in Whitehall, opposite the Horse Guards, as equal to the pavement in the Place de la Concorde, or in any part of Paris, and considering that its thickness is only half an inch, its having so long stood the traffic of so great a thoroughfare without any apparent change, except a greater smoothness of surface, is very remarkable.—*Times.*

NOTICES ON THE STEAM ENGINE, &c., IN REPLY TO CORRESPONDENTS.

We have been requested to correct certain alleged errors in our review of the Appendix E, F, to Tredgold, given last month. In reference to the engines of the Dee and Solway, a Greenock correspondent says—"The air-pump rods are cased with gun metal, and the iron at the lower end is secured by a brass flange jointed and screwed to the bucket, so that no part of the iron is exposed to corrosion from the salt water. The upper and under portions of the D valves are connected with three rods. (Is the writer of that article aware that Maudslays have only *one rod* in the engines of the "Great Western") The holding down bolts were made as requested by the engineer appointed to inspect the engines."

Our readers will probably recollect that our objection to the air-pump rods of these engines was, that they were cased at all. We have known instances in which this casing stripped off, and have been informed that some such accident did actually occur to the engines of the Dee or Solway. The expedient referred to by our correspondent, of covering up the end of the rod with a brass flange will, we fear, go but a little way in obviating the corrosion to which we adverted, for it is not at the extreme end of the rod, but at the neck of the rod, where any injurious corrosion takes place. The water insinuates itself to a certain depth between the brass of the bucket-eye and the iron of the rod, and eats its way up beneath the casing. We have known air-pump rods to be rendered unserviceable by this species of corrosion, when their extreme ends were comparatively uninjured.

The allusion to the practice of Messrs. Maudslay is, we suppose, intended to show that our strictures were shallow and hypercritical. Upon this point we shall leave our readers to form their own opinions, and shall content ourselves with expressing our gratification that Messrs. Scott and Sinclair have relinquished their old system in favour of that which we have all along recommended. It forms no part of our function to inquire at whose instance the holding down bolts, or any other part of an engine have been constructed in an objectionable manner; our purpose is not to find fault with any one particular party, but merely to express our conviction that certain practices are bad, and ought to be exploded. We war not with individuals but with errors.

Another Greenock correspondent informs us that the formula $15\left(\frac{1}{\theta}-\theta\right)$ given in the notes on "Steam Navigation" in our last month's number has been "altogether misapplied," because, indeed, we have alleged it to express "the rise or fall in temperature due to compression or rarefaction, without reference to initial density." Our correspondent favours us with an algebraic formula to prove his position, but our pages do not contain the allegation he charges upon them, we, therefore, think it needless to give the paper an insertion.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM NOVEMBER 25TH TO DECEMBER 22ND, 1842.

Six Months allowed for Enrolment, unless otherwise expressed.

Felix Napoleon Target, of Blackheath, gentleman, Leon Castelaine, of Backlane, Shadwell, chemist, and Adolphe Aubril, of Back-lane, aforesaid, artist, for "*a new method of refining or manufacturing sugar.*"—Sealed Nov. 25.

James Smith, of Coventry, card stamper, for "*improvements in weaving ribbons and other ornamented fabrics.*"—Nov. 25.

Charles Heard Wild, of Birmingham, engineer, for "*an improved mode of constructing floors for fire-proof buildings.*"—Nov. 25.

Isham Baggs, of Wharton-street, in the county of Middlesex, chemist, for "*improvements in producing light.*"—Nov. 25.

Frederick Oldfield Ward, of St. Martin's-lane, gentleman, and Mark Freeman, of Sutton, in the county of Surrey, gentleman, for "*improvements in candlesticks, apparatus, and instruments employed in the use of candles and rushlights.*—Nov. 25.

Pandia Theodore Ralli, of Finsbury-circus, wine-merchant, for "*improvements in the construction of railway and other carriages, and in apparatus connected therewith.*"—Nov. 25.

William Henry Fox Talbot, of Lacock Abbey, Wilts, Esq., for "*improvements in coating or covering metals with other metals.*"—Nov. 25.

Thomas Shansell, of Birmingham, agent, for "*certain improved machinery for cutting or shaping leather, paper, linen, lastings, silks, and other fabrics.*"—Dec. 3.

Ebenezer Timmis, of Birmingham, manufacturer, for "*improvements in apparatus used for arresting the progress of and extinguishing fire.*"—Dec. 3.

Edward Cobbold, of Melford, in the county of Suffolk, clerk, M.A., for "*improvements in instruments for writing or marking, part or parts of which improvements are applicable to brushes for water-colour drawing.*"—Dec. 3.

John Stubbins, of Nottingham, hosier, for "*improved combinations of machinery to be employed for manufacturing certain parts of articles in stocking or lace fabrics.*"—Dec. 3.

Don Pedro Pouchant of Glasgow, civil engineer, for "*a certain improvement or improvements in the construction of machinery for manufacturing sugar.*"—Dec. 3.

John Sealy, of Bridgwater, merchant, for "*an improved tile.*" Two months.—Dec. 3.

Charles Heard Wild, of Birmingham, engineer, for "*an improved switch for railway purposes.*"—Dec. 3.

Thomas Howard, of Hyde Chester, manufacturer, for "*improvements in machinery for preparing and spinning cotton, wool, flax, silk, and similar fibrous material.*"—Dec. 3.

William Hancock, Jun., of Amwell-street, gentleman, for "*improvements in bands, straps, and cards for driving machinery and other mechanical purposes.*"—Dec. 3.

Frederick William Etheredge, of Frindsbury, gentleman, for "*improvements in the manufacture of bricks, tiles, and other similar plastic substances.*"—Dec. 3.

William Henry Stuckey, of Guildford-street, Esq., for "*improvements in filtering water, and other fluids.*"—Dec. 3.

William Pope, of the Edgeware-road, ironmonger, for "*an improved stove.*"—Dec. 6.

William Oxley English, of Kingston-upon-Hull, distiller, for "*improvements in purifying spirits of turpentine, spirits of tar, and naphtha.*"—(A communication.)—Dec. 8.

William Coley Jones, of Vauxhall-terrace, practical chemist, and George Fergusson Wilson, of Vauxhall, gentleman, for "*improvements in operating upon certain organic bodies or substances, in order to obtain products or materials therefrom for the manufacture of candles and other purposes.*"—Dec. 8.

William Smith Harris and Septimus Hamels, both of Leicester, cotton-winders and copartners, for "*improvements in the manufacture of reels for reeling cotton and linen thread.*"—Dec. 8.

William Kempson, of the Borough of Leicester, manufacturer, for "*improvements in the manufacture of muffs, cuffs, ruffs, tippets, mantillas, pelerines, dressing gowns, boots, shoes, slippers, coats, cloaks, shawls, stocks, cravats, capes, boas, caps, bonnets, and trimmings for parts of dress.*"—Dec. 8.

George Purt, of St. Mary-at-Hill, soda water manufacturer, and William Hall of Woolwich, engineer, for "*improvements in producing aerated liquors.*"—Dec. 8.

Richard Barber, of Leicester, reel manufacturer, for "*improvements in the manufacture of boots, shoes, and clogs.*"—Dec. 8.

John George Bodmer, of Manchester, engineer, for "*improvements in the manufacture of metallic hoops and tyres for wheels, and in the method of fixing the same for use, and also improvements in the machinery or apparatus to be employed therein.*"—Dec. 8.

William Edward Newton, of Chancery-lane, civil engineer, for "*improvements in the construction and arrangement of axles and axletrees for carriages, carts, and other vehicles used on rail or other roads.*—(A communication.)—Dec. 8.

William Lomas, of Manchester, worsted-spinner, and Isaac Shimwell, of the same place, worsted-spinner, for "*improvements in the manufacture of fringes, cords, and other similar small wares, and also in the machinery or apparatus for producing the same.*"—Dec. 8.

John Grantham, of Liverpool, engineer, for "*improvements in the constructions and arrangements of the engines and their appendages for propelling vessels on water.*"—Dec. 8.

James Brown, of Soho, Birmingham, engineer, for "*improvements in steam engines and steam propelling machinery.*"—Dec. 8.

Benjamin Fothergill, of Manchester, machine-maker, for "*improvements in machines called mules, and other machines for spinning cotton, wool, and other fibrous substances.*"—Dec. 8.

Percival Moses Parsons, of Waterloo-road, Surry, civil engineer, for "*improvements in steam engines and boilers, and in motive machinery connected therewith.*"—Dec. 8.

Charles Keene, of New Bond-street, hosier, for "*improvements in the manufacture of hose, socks, drawers, gloves, mitts, caps, comforters, and cuffs.*"—Dec. 15.

William Palmer, of Sutton-street, Clerkenwell, manufacturer, for, "*improvement in the manufacture of candles.*"—Dec. 15.

Thomas Cardwell, of Bombay, in the East Indies, merchant, for "*improvements in the construction of presses for compressing cotton and other articles.*"—Dec. 15.

Moses Poole, of Lincolns-inn, gentleman, for "*improvements in dressing mill stones.*—(A communication.)—Dec. 15.

Charles Maurice Elizee Sautter, of Austin Friars, in the City of London, gentleman, for "*improvements in the manufacture of sulphuric acid.*"—(A communication.)—Dec. 15.

Guillaume Simon Richault, of the Sabloniere Hotel, Leicester-square, editor of music, for "*improvements in apparatus for exercising the fingers of the human hand in order to facilitate their use in the playing of the piano forte and other instruments.*"—(A communication.)—Dec. 15.

James Winchester, of Noel-street, hatter, for "*improvements in steam boilers, and in the methods of applying steam or other power to locomotive purposes.*"—Dec. 15.

Edward Robert Rigby, and Charles John Rigby, of Gracechurch-street, brush manufacturers and copartners, for "*improvements in the manufacture of certain articles in which bristles have been or are now used.*"—Dec. 21.

Gabriel Hyppolyte Moreau, of Leicester-square, gentleman, for "*improvements in propelling vessels.*"—Dec. 21.

Gabriel Hippolyte Moreau, of Leicester-square, gentleman, for "*improvements in steam generators.*"—Dec. 21.

John Squire, of Ponghill, Cornwall, engineer, for "*improvements in steam boilers or generators.*"—Dec. 21.

Taverner John Miller, of Millbank-street, Westminster, oil merchant, for "*improvements in apparatus for supporting a person in bed, or when reclining.*"—Dec. 21.

William Bridges, of Birmingham, button-tool-maker, for "*improvements in buttons.*"—Dec. 21.

Henry Purser Vaile, late of Fleet-street, gentleman, for "*improvements in combining mechanical instruments for obtaining power.*"—Dec. 22.

Joseph Beaman, of Smethwick, Stafford, ironmaster, for "*an improvement in the manufacture of malleable iron.*"—Dec. 22.

William Godfrey Kneller, of Wimbledon, chemist, for "*improvements in the manufacture of soda in the evaporation of brine, and in the concentration and manufacture of sulphuric acid.*"—Dec. 22.

Robert Wilson, manager at the works of Messrs. Nasmyths Gaskell and Co., at Patricroft, near Manchester, engineer, for "*improvements in locomotive and other steam engines.*—Dec, 22.

James Morris, of Cateaton-street, merchant, for "*improvements in locomotive and other steam-engines.*"—Dec. 22.

THE VARIATION OF THE COMPASS.

Observations made at the Royal Observatory, Greenwich,

G. B. AIRY, Astronomer Royal.

Mean Magnetic Declination for the month of September, 1842—23° 14′ 11″

The observations of the Magnetic Dip are suspended, when they are resumed the results will be recorded as usual.

NEW HYDROSTATIC ENGINE.—At the Taff Vale Railway, we learn, by the *Cambrian*, that a very complete hydrostatic engine is now at work, for the raising and tipping of coal, to be shipped from the terminus of the Taff Vale Railway, at the Bute Docks, Cardiff. It is only just set to work, but exhibits the principle of the hydrostatic balance very beautifully, and with the most perfect practical results.

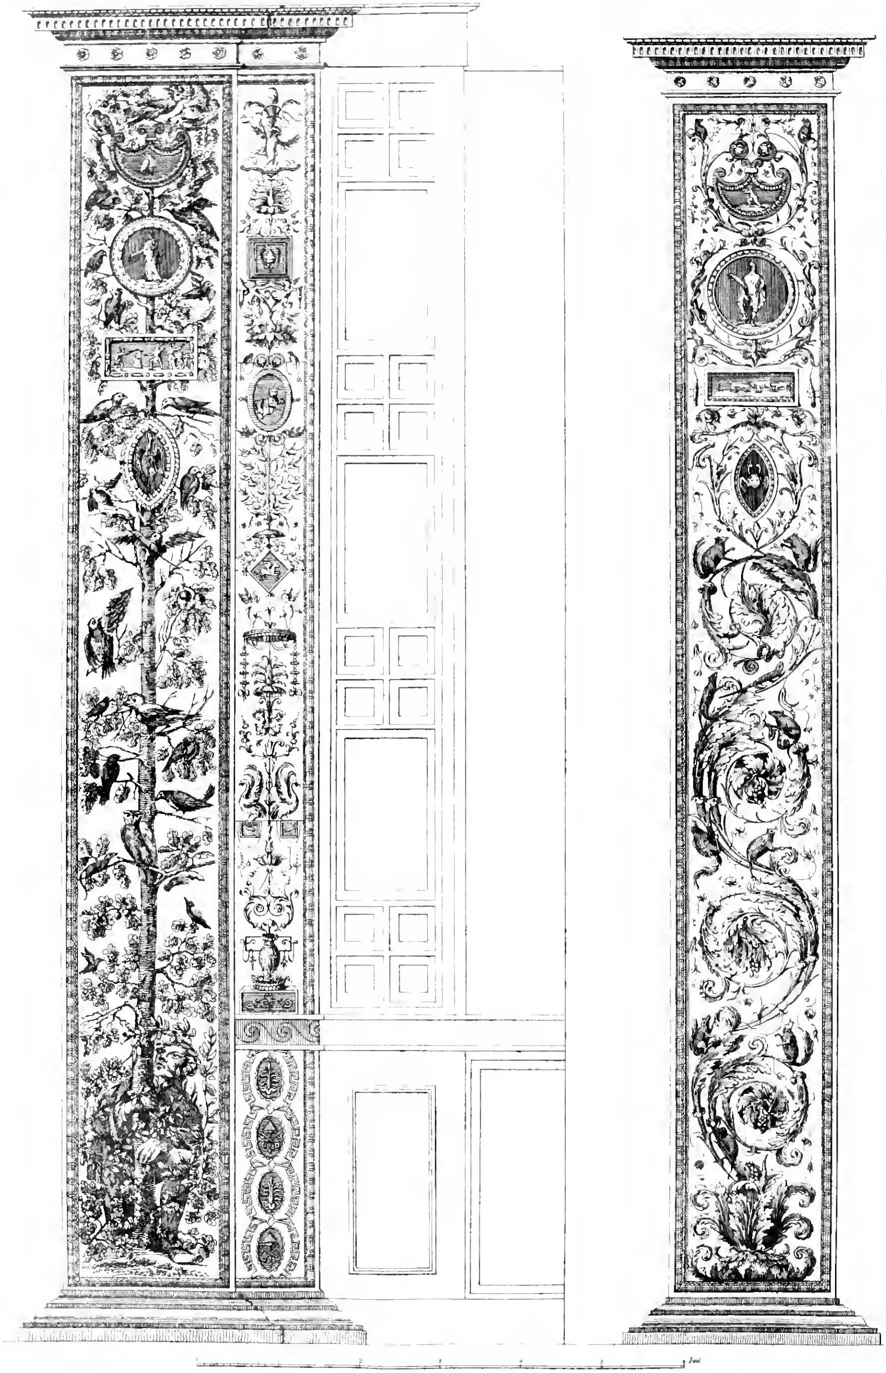
ARABESQUE DECORATIONS OF THE VATICAN AT ROME.

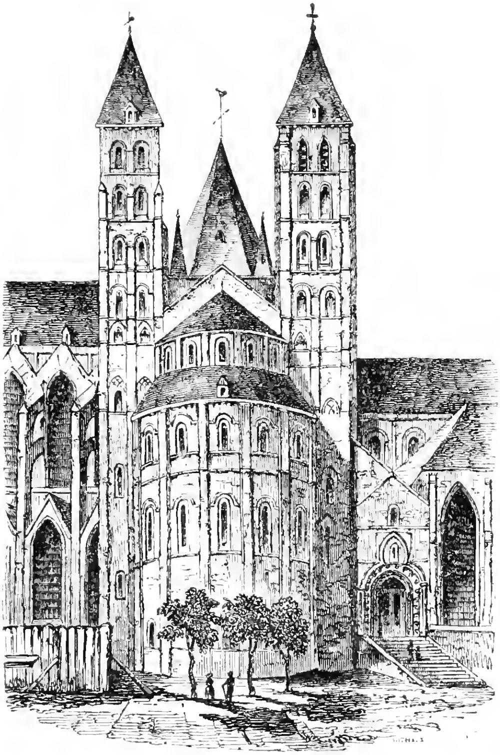


BUILDINGS IN BELGIUM.

By George Godwin, Jun., F.R.S., &c.

"Perhaps no study reveals to us more forcibly the social condition and true feeling of passed generations than that of their monuments."—M. Guizot.

Chapter II.



Concerning the age of the Cathedral, there has been some controversy. Monsieur B. C. Dumortier, a member of the Belgic Chamber of Representatives and of the Royal Academy of Brussels, (and in company with whom the writer had the good fortune to examine the building) published first in 1837,[1] some remarks on the Cathedral, and then in 1841, a second pamphlet,[2] with a view to prove that the nave of the existing building belonged to the 6th century. These essays display much learning and ingenuity, but more enthusiasm, and this latter has served to blind the writer to all that militated against his desire to obtain unlimited reverence for his favourite building, and like an unruly Pegasus, has carried him far away from the goal he sought, namely the truth. Absence of direct statement by early writers that the nave was destroyed, serves to prove to M. Dumortier, (as in some similar cases it has been urged by other continental antiquaries) that it has not been rebuilt, and so far from the fact that pointed arches form an essential feature in it being deemed sufficient to weaken his opinion, it is proof strong as holy writ that the system of pointed architecture arose in Belgium, and that in the cathedral of Tournay is to be found its first out-budding. In confirmation of his opinion, M. Dumortier informed me, that a charter had been recently discovered dated 1257, proving that the architect of Cologne Cathedral was a Belgian. It sets forth that the monks of Cologne, in consideration of the services performed by Master Gerard, of St. Trond (*Gerardus de Sancto Tradone*), in directing the construction of their Cathedral, had assigned to him a certain estate of land.

Although apart from the present purpose, I cannot avoid repeating here a portion of the King of Prussia's speech when laying the first stone of the new works in completion of the last mentioned wonderful building. "Here where the ground stone lies," said the king, "here by these towers, will arise the noblest portal in the world. Germany builds it—may it be for her, with God's will, the portal of a new era, great and good. Far from her be all wickedness, all iniquity, and all that is ungenuine and therefore un-German. May dis-union between the German princes and their people, between different faiths and different classes, never find this road; and never may that feeling appear here, which, in former times stopped the progress of this temple—aye, even stopped the advance of our Fatherland. Men of Cologne, the possession of this building is a high privilege for your city, enjoyed by none other, and nobly this day have you acknowledged that it is so. Shout, then, with me, and while you shout will I strike the ground-stone,—shout loudly with me your rallying cry, ten centuries old, "Cologne for ever!" And then, while a thousand voices reechoed "Cologne for ever!" the ancient crane on the top of the south tower was once again put into motion, and was seen slowly raising a ponderous stone. The amount both of time and money required to complete the Cathedral renders the issue somewhat doubtful. Let us hope, however, that this fear may be unfounded, and that this magnificent building may gradually gain its intended proportions—an emblem of unity, a worthy offering to God, and an ornament to the world.

To return, however, to Tournay; there is sufficient evidence to induce the belief that the Cathedral was founded at the end of the 3rd century, and rebuilt about the middle of the 5th century, with the aid of Clovis, by St. Eleutherius. Chilpéric in 578, endowed the Cathedral largely, and his original deed of gift "*cum sigillis*," remained amongst the archives of the chapter until they were burnt in 1566.[3] Louis le-débonnaire added to the cloisters of the Cathedral in 817, and Charles the Simple further endowed it. Soon after this, however, namely in 882, the Normans ravaged Belgium with fire and sword, and inspired such universal dread, that the people, adding to their prayers "from the fury of the North-men, Good Lord deliver us," fled in all directions. Tournay, rich and important as it then was, did not escape; the walls and the chief buildings were destroyed, and the inhabitants were forced to abandon the town, to which it seems they did not return until the beginning of the 10th century. At the time of this invasion there can be little doubt the Cathedral was pillaged, and partly if not wholly demolished; and it is probable that its re-erection was not attempted until quite the close of the 10th century, in which the inhabitants returned, or rather the beginning of the 11th. All analogy shows that earlier than this, the nave and transepts could hardly have been commenced, and that it was probably much later before they were completed.[4] If analogy, however, were deemed insufficient to remove

1 "*Revue de Bruxelles*," Dec. 1837.

2 "*Dissertation sur l'age de la Cathédrale de Tournai*." *Bruxelles*, 1841.

3 The deeds must have been very numerous, if we believe a contemporary writer, who says that the melted wax from the seals formed a stream down the hill.

4 It is but fair towards M. Dumortier to give, in his own words, his argument against the assumed destruction of the Cathedral by the Normans.—

"L'histoire de la translation du corps de Saint Eleuthère sous l'évêque Hédilon en 876, immediatement avant l'invasion des Normands, nous fait connaitre qu'à cette epoque l'on avait démoli la chapelle de Saint Etienne, qui etait situee à la suite de la cathédrale. Voici comment s'exprime la chronique écrite au XIe siecle: *Presulatum tornacensis ecclesiae Hedilone viro prudenti et justo possidente, basilica beati Stephani prothomartyris, quae sita est post ecclesiam Christi genitricis semperque virginis Mariae, destructa est.*

Le soin que prend le chroniqueur à nous apprendre la destruction de la chapelle de Saint Etienne annexée (?) à la Cathedrale, indique clairement la conservation de celle-ci. Si ce vaste monument, dont l'existence est demontrée et au VIe et au IXe siecle, avait ete detruit lors de l'invasion des Normands, le chroniqueur se serait-il borne à nous apprendre la destruction d'une de ses parties? C'est ici que s'applique se vieil adage: *inclusio unius, ex-*

Elevatio corporis beati Eleutherii tornacensis episcopi et confessoris; MS. in Libro Sancti Martini Tornacensis.

5

the ground for controversy respecting the age of the cathedral, it would seem to be destroyed by the recent discovery of a M. S. entitled "*Ritus Officii divini ecclesiæ Tornac*," and dated 1656. This gives a list of the various fêtes formerly celebrated in the Cathedral, and points out the 9th of May (which was then annually celebrated), as the anniversary of the dedication of the church, in the following words: "*Dedicatio ecclesiæ, est festivus dies in populo intrà muros. Triplex est cum octavâ et duplex primæ classis;*" and then, "*Vidélicet novæ, anno* 1066." Monsieur T. Le Maistre d'Anstaing, who mentions this MS. in his very interesting work on the Cathedral,[5] remarks that doubtless there were more consecrations than one, as for example that of the choir, and those after partial restorations; but that this being the first, was properly regarded as the most important, and, being duly observed, had been handed down to the date of the MS. alluded to.

In a comparatively short space of time after this date, if the historian Jean Cousin is to be believed,[6] the choir becoming too small and probably being injured by the events of troublous times, was cleared away to make room for a more magnificent structure. Cousin states, that the first stone of the new choir was laid in 1110; and that it was finished about 80 years afterwards or more. His authority for this statement, however, does not appear. According to certain old chroniclers quoted by M. d'Anstaing, it was vaulted in 1242, at the expense of Walter de Marvis; but it would seem that divine service had been performed in it previous to that date, its dedication being ascribed to the year 1200.

At the end of the twelfth century, pointed architecture was but just developing itself, so that we must conclude either that the choir of the Cathedral of Tournay is one of the earliest monuments of that style, or that the received statements are erroneous. I am inclined to believe the former.

In concluding these remarks on the Cathedral of Tournay, it is gratifying to be able to say, that the sum of £20,000 has been voted by the nation (to be expended in ten years) for the restoration of this noble building, and that under the direction of M. Renard, the architect, there is every reason to expect it will be carried out efficiently.

When speaking of the Town Hall at Louvain, the writer intended mentioning, that what is stated to be the original drawing of the west front of the Cathedral of that town is preserved there, together with a very elaborate and beautifully executed model of the same in stone as it was executed, with a singularly lofty tower and spire in the centre, and another on either side of it; only one of the side towers, however, is shown. The drawing is on vellum, 9 ft. high and 2 feet 9 inches wide, and is coarsely but carefully executed. The model is about 24 feet high and 7 feet 6 inches wide at the base, and is now in an excellent state of repair. The centre spire, which is said to have been above 500 feet high (an extraordinary elevation, exceeding, by 100 feet, that of the spire of Salisbury Cathedral) was destroyed in 1606 by a storm, and in its fall ruined the side towers.

The interior of the Cathedral affords an excellent specimen of pointed architecture. The choir is separated from the nave by a highly decorated rood-loft of three arches with numerous sculptured figures under canopies. Above the loft is a rood of very large size, with figures of the Virgin and St. John at the foot (without which a rood was not deemed complete) profusely adorned with colours and gilding.

The font, situated at the west end of the nave, has an elaborate Gothic crane of iron attached to the wall near it, for the purpose of supporting the cover, now removed. One of the chapels in the north aile of the nave has a balustrade or low screen of coloured marbles, exquisitely sculptured in the style of Louis XIV. And under the arch which separates the choir from its side aile, on the north side of the grand altar, is a sculptured stone tabernacle of very elaborate richness, reaching the whole height of the arch, perhaps about 30 feet. It is a hexagon in plan, tapering upwards to a point, and is supported on six small pillars round its circumference, and one in the centre.[7]

The pulpits found in the Belgic churches are in many cases remarkable for their large size, the profusion of materials employed, and their elaborate workmanship, rather than for good taste and propriety. The pulpit in the cathedral under notice (situated as most of them are, on the south side of the nave) represents the conversion of St. Paul. The saint and his horse are on the ground; on the west side of them stands the figure of a man gazing with astonishment, if I remember rightly, at the miracle; a huge mass of rocks and trees supporting angels and birds forms the chair itself. Behind rise two lofty fir trees, from the stems of which, about midway, extends the canopy or sounding board, adorned with angels and other carved decorations.

The pulpit in the Cathedral at Malines (a most interesting town) represents the same subject, but is differently arranged. St. Paul and his horse are on the ground at the foot of a mass of rock forming the body of the pulpit. Our Saviour on the cross, the Virgin, and other figures, enter into the composition; a stem of a fallen tree serves as a rail to the stairs: and a continuation of the rock work, from which the Holy Spirit in the shape of a dove, descends over the head of the preacher, forms the canopy.

In the church of St. Andrew, at Antwerp, the pulpit represents Andrew and Peter called from their nets by our Saviour. It is ascribed to Van Hool and Van Gheel. The pulpit in the Cathedral of the same city is a curious composition, consisting of twining shrubs and birds, said to be the work of Verbruggen. This artist also executed the pulpit in St. Gudule, at Brussels, which represents the expulsion of Adam and Eve from Paradise, and is perhaps better known than any of those I have already mentioned. The pulpit at Nôtre Dame, in Brussels, is a representation of Elijah fed by ravens. In some cases part of the sculpture is in wood and part in marble; as for example, in the Cathedral at Ghent, where the pulpit is of large size and elaborate design, embracing many figures.

In 1838 the writer laid before the Royal Institute of British Architects, a series of drawings illustrative of the ruins of the ancient monastery of St. Bavon in the city last mentioned, namely Ghent. These remains are situated in the old citadel on the eastern side of the town near the Antwerp Gate, a quarter not generally visited. They consist chiefly of a large rectangular building unroofed, the remains of cloisters, and a small octagonal building of two stories, (known as the chapel of St. Macaire) communicating with the cloisters and standing within the square court surrounded by them. The accompanying sketch (Fig. 3,) represents the interior of the lower story of the chapel which is much more perfect than any other part of the building. It is vaulted with rubble stone with flat shallow ribs diverging from the centre, and terminating in large corbels of columnar form. The vault has been covered with stucco, and ornamented with colours, now for the most part destroyed. One of the eight sides of the building is wider than the others, for the purpose of admitting a double archway of the cloisters, and a second side is occupied by an

---

clusio alterius. Ainsi il demeure démontre que la Cathédrale de Tournai ne fut pas detruite à cette époque. et qu'elle resista à l'invasion Normande. En effet. celui qui a vu ce noble edifice. et considere l'épaisseur des colonnes de sa partie romane, la solidité des materiaux employés a sa construction, n'hésitera pas à reconnaitre qu'avec de tels materiaux il existait des conditions de durée que l'on ne retrouve pas dans les églises des provinces Rhenanes. et qu'ainsi s'explique pourquoi Nôtre Dame de Tournai a pu résister à une époque où tant d'autres édifices religieux ont succombe. Au lieu d'être construite comme les eglises des bords du Rhin en un calcaire sablonneux. friable et de peu de duree, la basilique de Tournai est construite en calcaire anthraxifère. espèce de marbre tres dur, et faisant feu sous le briquet. Pour detruite un édifice aussi gigantesque, et composé de pierres aussi solides et aussi massives, il faudrait de milliers d'ouvriers et un travail de plusieurs années. Or, les Normands avaient toute autre chose à faire que de passer leur temps à un tel ouvrage. Aussi, tous les chroniqueurs et les historiens de Tournai ont parlé de la Cathedrale, et l'on ne trouve, dans leurs écrits, aucune indication d'où l'on pourrait induire que ce vaste monument aurait eté détruit et reconstruit à la suite de l'epoque carlovingienne. Au contraire, preuve certaine que l'édifice etait dejà bien vieux à cette epoque. il est constant que le chœur roman fut démoli vers la fin du XIe siecle. et qu'en l'an 1110. l'on commença la construction du chœur actuel, l'un des monuments les plus vastes et les plus hardis de l'art gothique."

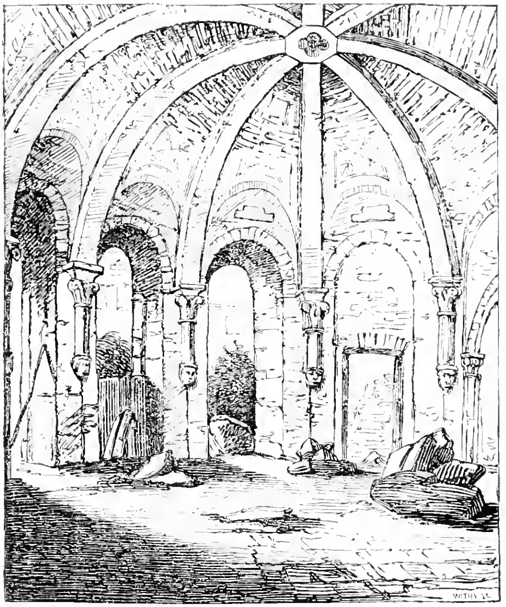
6 "*Histoire de Tournay par Jean Cousin.*" *Douay. MDCXX.*

7 In the church at Leau, a place little known, there is a tabernacle of somewhat similar outline in the style of the *Renaissance*. and of very extraordinary workmanship.



altar, the top stone of which is marked, as is often the case with ancient altar stones, with five small crosses, one at each corner and one in the centre, the latter being the larger.[8] Each of the other sides has a semi-circular arched way in it. The building is paved with black and red tiles about 4 in. square each.

In the rectangular building and cloisters which present the work of several periods, the columns where they remain are very short, and have leafed capitals similar to some in Tournay Cathedral. They are formed of the grey Tournay stone, and in some few instances have octagon shafts as is also the case in the Cathedral. The arches of the cloisters were pointed; they were formed of brick, with stone ribs and corbels (sculptured with foliage and figures), and were of more recent date than the walls. The rectangular building is paved with red, yellow, and black, glazed tiles of various shapes and sizes (some being very small) disposed in patterns.[9]

The history of this building ranges over a considerable period. In the year 636, King Dagobert of France, sent St. Amand to Ghent to preach Christianity. St. Amand having made many converts, founded two monasteries, one of which was on the site of the remains in question. A few years afterwards, Allowin, surnamed *Bavon*, was induced by the teaching of St. Amand to quit the world, and having given the whole of his property to the latter monastery, obtained permission to construct a cell in the neighbouring wood, where he died in 654. The monastery then took his name, a church was dedicated to him, and the whole quarter was termed, for many years, the town of St. Baven. In 846, the monks fled to avoid the Normans, and took refuge in England. John of Gaunt was born in this monastery in 1311, and at the beginning of the 16th century the whole establishment was destroyed, in order to construct a citadel on the site.[10]

In the "*Notice Historique de Gand*" it is stated that in 1067, Baudouin, Bishop of Noyon, and Liebert, Bishop of Cambray, consecrated the church of St. Bavon, and deposited there, in a private chapel, the relics of St. Macaire, who, it was supposed, had freed the city from the plague by his prayers, some few years before. The style of the octagon building before mentioned, still called the chapel of St. Macaire, agrees with this date satisfactorily.[11]

[8] The crosses upon ancient altar stones were intended to mark the spots anointed with chrism at its dedication. A Pontifical printed at Rome in 1595, and now preserved in the British Museum, shows that a bishop when consecrating a church, was enjoined to mark with his thumb dipped in the chrism, twelve crosses on the walls of the church, and others on the door, altar, &c. See *Archaeologia*, vol. XXV, p. 243, 275.

[9] The area of the cloister is about 100 feet square; the diameter of the octagonal building is about 20 feet.

[10] The abbot and monks were removed to the cathedral church of St. John the Baptist, in the city of Ghent, from that time called the church of St. Bavon.

[11] I cannot omit mentioning with reference to Ghent, that M. L. Roelandt to whom the city is indebted for many important buildings, (amongst them the most elegant little theatre and ball-room that I know of,) is engaged upon a new *Palais de Justice* of large extent. The window dressings of the principal floor have more than ordinary importance given to them, and form a principal feature in the façade. They consist each of two disengaged Corinthian columns supported on corbels, with entablature and pediment, and corresponding pilasters on the face of the building.

CANDIDUS'S NOTE-BOOK.
FASCICULUS XLV.

"I must have liberty
With al, as large a charter as the winds,
To blow on whom I please."

I. ALTHOUGH not propounded *ex cathedrâ*, the doctrine broached by the Premier Professor, has made quite a sensation, filling all with surprise, and some with a panic feeling. It is the opinion of more than one in the profession that our architectural Professors are nearly all bewitched. As if it was not enough to have Hosking preach down Vitruvianism, we have now Cockerell preaching up rank architectural Radicalism. He goes to the extent of turning every thing topsy-turvy, without regard to those most comfortable of all things—our prejudices. What is to become of our reverence for precedent and authority, if copyism is henceforth to be proscribed, and every one expected to give us his own ideas. It may be all very well for those who possess taste, and have ideas of their own; but then what is to become of those poor devils who have none? If they must neither borrow nor steal, their fate will be hard indeed. While Professor Pugin would merely lead us back to the "dark ages," bidding us look for light and enlightenment there, the Royal Academy Professor would fain turn us adrift, to grope about in more than Egyptian darkness. Surely it is better to be tethered to a stake with a yard or two of rope, than to have the precious liberty of rambling at will blindfold among pitfalls and precipices. So, at any rate, think some. After copyism has served them so well, they must now hear it reviled by the ugly epithets of "dull" and "unmanly"! and that by a Professor, too! Why, he might as well have called it *stupid* and *old-womanish*, for that was, no doubt, his meaning. As to *invention*, that is, of a truth, most venturesome work, but then, be it remembered,

"Things out of hope, are compass'd oft by vent'ring."

II. It argues very great forbearance on the part of Welby Pugin that he has not had a fling at Abbotsford, for it is certainly quite as miserable and trumpery as any of the architectural "monstrosities" he has shown up in his "Contrasts," or quizzed in his "True Principles," although concocted out of the ideas of so many persons who were successively consulted by the "Great Magician," but who have shown themselves to be no conjurors. Stark, Terry, Burn, Blore, Atkinson, all prescribed in turn, and bedoctored till they bedevilled it. Whichever be the best of Scott's works, Abbotsford is decidedly his worst—mere "Carpenter's Gothic," and a "Tea-Garden Castle." Fortunate would it be for the credit of his own taste, and also for the credit of those employed upon that pet fancy of his, were it to be demolished at once, instead of being piously preserved as a monument of Scott's *virtuosity* in architecture. Attempts in the Gothic style by Scotch architects are almost without exception intolerably bad, many of them utterly contemptible. Taymouth Castle, about which the newspapers made so much fuss a few months ago, is in point of architecture, most miserable. The noble owner of that big house possesses an infinitely superior specimen of architecture in a small one called the Forest Cottage, which he has lately erected in Inveroran. Homely in character, as its name denotes, yet at the same time something more than a mere cottage, it idealizes that character most happily, bringing forward some of its most picturesque traits, without any paltry affectation. It is withal eminently picturesque, which is more than can be averred of those things which pretend to be "Picturesque" by title, and for the nonce.

III. That the lord of Abbotsford himself could be sufficiently severe upon other persons' architectural whims, is evident from a postscript of a letter of his to Mr. Morritt, of Rokeby Park, and who was then at Brighton; saying, "Will you do me a favour? Set fire to the Chinese stables, and if it embrace the whole of the Pavilion, it will rid me of a great eye-sore" !! As this was written in the February of 1826, immediately after the crash that laid low his fortunes, and reduced him to beggary—at any rate to that sort of nominal beggary which thousands would call luxurious affluence—hardly is it to be supposed that his so expressed opinion of the Pavilion at Brighton was a mere sally of wantonness and *gaîté de cœur*. The Pavilion might have been rendered a good specimen of the style it pretends to, and so far have been satisfactory, whatever may be objected to the choice of such style for such purpose. Instead of which it is a finical and insipid, not to say paltry imitation of that style, with little character than that of toyishness and gimcrack, certainly with no "heartiness of character" about it, nor any *gusto*. The "pimping pagoda taste" of George IV. is not yet extinct in the family, for a Chinese conservatory, or something of that sort, is now erecting in the gardens of Buckingham Palace, but whether it is of porcelain, or common crockery quality, is not said.

IV. Were the reviewers to pay Mr. Gwilt in his own coin, they would say nothing of his book, except that, being the work of a living contemporary, delicacy prevented them from expressing any opinion relative to it; besides, their silence would be far more gratifying than any remarks, however complimentary, from a class of critics whom Mr. Gwilt himself denounces as a set of meddling blunderers and blockheads. He has shown himself most dreadfully sore upon the subject of reviewers and anonymous criticism, and for no other reason, it appears, than because an article in the *Foreign Quarterly* spoke in commendation of Schinkel and the German school of architecture. Any other person than Mr. Gwilt would have been thankful for the information there first conveyed upon the subject, whether he agreed with all the writer's opinions or not: whereas the meek Joseph assailed him as virulently as if that article had been a personal attack upon himself, and spluttered in a very big strain about "small fry" writers and anonymous critics—or rather those who set up for critics, though utterly ignorant of the subjects they profess to treat. Does Mr. Gwilt then suppose that professional men never write in literary journals, on subjects connected with their own pursuits? Is he not aware, poor man, that among the anonymous scribblers in the periodical he fell foul upon, there was no less a nobody than Sir Walter Scott? Can he be so ignorant as not to know that Cowper, Byron, Southey, Moore, Hallam, Brougham, Horner, the Rev. Sydney Smith, not to mention Bishops, have been anonymous reviewers? It will be well for him should he not find out at last, that it had been better had he condescended to publish anonymously, himself. None will envy him the fame he will now get by not doing so.

V. "Nothing is so tiresome," says Sir Walter Scott, "as walking through some beautiful scene with a *minute philosopher*, a botanist, or pebble-gatherer, who is eternally calling your attention from the grand features of the natural picture, to look at grasses and chucky-stones." *Mutatis mutandis*, this may be applied to those minute critics in architecture who attend chiefly to inferior matters, such as the proportions or correctness of an order as an order, without regard to any further effect, or its coherence with the rest of the building. Any thing of that kind which happens not to be in distinct conformity with standard, and therefore only general, rules,—which we are rather to be guided by than tied down to, is at once pronounced by them to be faulty and incorrect, yet at the same time they can tolerate infinitely greater faults, far more reprehensible licenses, and that which is the greatest defect of all, let the style be what it may, the utter want of all artist-like feeling. By a minute critic, however, is not to be understood one who examines merely the minutiæ and details of a building—for that is more than every one of the tribe is capable of doing: but one who looks at every thing piecemeal, and who dwells exclusively upon individual particulars and detached circumstances, without taking into consideration whether there be any thing to call for, to justify, or to account for what he only perceives to be uncommon. Your minute critic is generally a staunch stickler for precedent, and not without reason, since precedent and authority are the crutches which help him along. Deprived of their aid, he comes to the ground. In any case out of the ordinary course he feels quite *put out*, and unable to make any thing of it, takes his revenge by pointing out what does not accord with usual practice, and therefore, as he will have it, a blunder or a solecism. How the minute philosopher chuckles when he detects some *homœopathically* small infringement of a mere pettifogging rule. Yet how obtusely blind is he apt to show himself in regard to every thing which does not come within the compass of rules and routine.

VI. By no means would it be amiss were public spirit and architectural zeal to be displayed in completing and giving the finishing touches to some of our modern buildings, as well as in the restoration of decayed ones. Many there are which admit of being greatly improved by corrections, and by omissions in them, more or less obvious, being supplied. Such is certainly the case with the National Gallery for one, and there even seems to have been some idea at one time of doing something more to that building, Barry having actually been consulted on the subject. Greatly might the United Service Club House be improved by giving it a cornicione, and throwing more spirit and richness into its other features. Nay, perhaps even the Conservative might be converted into a tolerably satisfactory design, were *carte blanche* for such alteration to be granted to some one who possessed both ingenuity and taste. At all events we may now expect to find that that building has served as a wholesome warning to the architects of the forthcoming new Conservative Club House in St. James's Street, and that they will show themselves Radical Reformers in point of architectural taste.

EXPRESSION IN ARCHITECTURE.

The expression, or as it is sometimes termed, the language of architecture, is a subject which has engaged the attention and employed the talents of many writers, both amongst professors of the art and others, nor is it at all uncommon to hear it said that every building which makes any pretensions to style and taste, should express by its design and character, the purpose for which it is intended. Although it is by no means my intention to deny that buildings of almost every class are capable of great and varied expression, yet to suppose that this expression may be varied so as to indicate all the different purposes of modern buildings appears to me as absurd as to deny all power of expression to the art. The characters of sublimity, majesty, grandeur, gaiety, or gloom, may be and frequently are imparted to a structure by the skill of its designer; but this is very different from the building indicating the intended purpose of its erection. We may see this by considering that gloom and solemnity are features equally characteristic of a prison or of a tomb, that grandeur and majesty are qualities of expression as appropriate in a palace as in a senate house, whilst gaiety and elegance are generally considered as characters equally to be impressed on the decorations of the private house and of the theatre. A great number of buildings must, indeed, always share in the same external style and expression, though erected for and adapted to very different purposes. We might as well expect the face of each individual whom we meet to express his particular pursuit and profession, and lay open to us his thoughts and intentions, as to look upon the façade of a building as the index of the purposes for which it was erected. The human face, indeed, is considered, and with unquestionable propriety considered as the index of the soul, as the outward sign by which we may read the feelings of the man, and being accustomed from the dawn of reason, perhaps intuitively, perhaps from experience acquired in infancy, to consider the features as indicative of the various passions, and our more mature years confirming this experience, we become so firmly convinced of the truth of these principles as to rely on the inferences we draw from them; and believing all men subject to the same feelings, the same joys and sorrows as ourselves, we make no distinction in our application of them; but consider, that whatever may be a man's rank, his race, his station, or his name, without regard to climate or complexion, whether he be an inhabitant of the polar circles, or the torrid zone, we may read in his face the passions of his soul. But though he may thus plainly and universally read the feelings of the man, the cause of those feelings is yet hidden from us; and although the expression of the features we look upon may induce in us corresponding emotions, we are unable to divine its origin. We may thus see the emotions of joy or fear spread rapidly through a crowd ignorant of their cause; each individual being immediately affected by his neighbour's animated look and gesture, or though himself remote from danger, becoming at once alarmed by the fear expressed in surrounding faces, which indicate that something unknown is to be dreaded, by its portentous indistinctness, rendered yet more fearful. In the arts of painting and sculpture, the artist copying the human face and figure, gives to his productions the expression he may choose, and in proportion to the intensity of that expression is the emotion raised, but the cause of such expression is sought for in the accessories, or combinations of the piece; and our experience of human feelings leads us to judge whether the passion expressed is in accordance with its exciting cause. If then in these most expressive arts the feelings excited do not lead us to the reason which induced the artist to give such particular expression to his work, if we are liable to be deceived in interpreting the meaning of allegorical painting and sculpture, how shall we in architecture, where neither nature nor experience teach us to decide, how shall we say what particular character shall indicate a particular building. We have here no standard of expression; the ideas of different nations on this subject are as various as their languages: and in examining the remains of ancient edifices, we do not decide upon the purposes for which they were built, from their architectural character, but the acccessories and combinations of their construction.

The Gothic style, which is by us considered as peculiarly characteristic of a church, would most assuredly not be viewed in the same light by an ancient Greek. One of our large churches, or cathedrals, would unquestionably produce emotion in the breast of any man who had a soul to feel; but this, I am persuaded, would arise from the grandeur of the structure, from the insignificance into which the spectator sinks while gazing through "the long drawn aisle," or looking up to the "arched and ponderous roof," and from the majestic evidence of superior constructive skill around him, and not from any feeling that such a style proclaimed, by its silent but unerring expression, that he was in the House of God. As on the human face we may read the feelings of the mind, may trace gaiety, gloom, resolution, or despair, so may we be impressed by the design of a building with the emotions corresponding to sublimity, grandeur, magnificence, or elegance; but as we cannot determine the cause of the passions expressed upon the human features, so we cannot impart to any structure, vary its character as we may, the power to express whether it be a temple, a palace, a senate-house or an exchange. And as mankind differ as to the expression proper to be given to a statue or a painting, so will they disagree as to the character proper for a building, nor can we hope that architecture shall speak in the same language to us all, until all shall not only have been educated alike but shall have acquired the same prejudices, habits, tastes, and feelings.

A. D.

THE VELOCITY OF WATER IN VERTICAL PIPES.

We have received a voluminous communication from Mr. Shuttleworth, purporting to be a reply to the notice in our December number, of his system of railway propulsion. The extreme length of his letter, which occupies thirty closely written pages, would be a total bar to its insertion, even were it an argumentative treatise instead of being almost entirely discursive. We have received from another correspondent, however, a communication on the same subject, deserving much more attention, in which the writer states argumentatively his objections to two of the positions introduced incidentally in the article on Mr. Shuttleworth's hydraulic railway. The question of the velocities acquired by water flowing down vertical pipes is, indeed, important and interesting; we shall therefore, after allowing our correspondent to speak for himself, pursue the inquiry, not only for the purpose of defending our previously expressed opinions, but with the view of arriving at some satisfactory conclusions on a subject that has given rise to much discussion, and respecting which, as it appears to us, very erroneous notions continue to be entertained.

The following is the letter to which we refer.

"*London, December* 21*st*, 1842.

"Sir—Agreeing with the writer of the remarks on Mr. Shuttleworth's Hydraulic Propulsion system, which appeared in your *Journal* of last month, that it is a pity to see so much talent, ingenuity, labour and expense lavished upon an invention evidently impracticable, I must at the same time call into question the reasoning by which the writer has arrived at this conclusion, or at least that part of it which relates to the flowing of water through a vertical pipe; I do so more particularly, as the subject is important, and, I believe, new: also because, from the editorial character of the article, it might mislead many of your readers. I shall endeavour to show that the writer has committed two important errors in the fifth paragraph of that article; first, in explaining the uniform flow of the water in the column, by the cohesive attraction of the particles of water. Secondly, in saying that this uniform velocity is *half* that due to the height of the column of water flowing through a *small* orifice, he appears to think that, supposing the height of the water constant, the issuing velocity diminishes as the aperture increases. Now, it is evident that such is not the case, as by increasing the diameter of the orifice, the friction of the sides decreases in a greater ratio than the area of the orifice increases. This is so evident, that I believe it requires no further explanation.

"Assuming the Irishman's privilege of going backwards, I shall first endeavour to demonstrate the second error, by proving the velocity of the issuing water (and therefore, as will be proved in the second part) of the whole column, to be expressed by the formula $8\sqrt{x}$, where x expresses the height, modified by the resistance of the air and friction. The friction, however, may be omitted, as being very trifling in a vertical pipe, when compared with the retarding effect of the atmosphere.

"When the water first enters the pipe, there is a slight decrease of velocity, in consequence of the "*vena contracta*," which in all works on hydraulics, is generally allowed for, by changing the 8 in the above formula to 5; it then assumes a vertical direction, its velocity increasing as the square root of the height, until the resistance of the air, increasing as the square of the velocity, becomes equal to the momentum of the water. An equilibrium then existing between the accelerating and retarding forces, the velocity would be uniform. As will be seen from the following equations, it would require an immense length of *vertical* pipe before this uniform velocity could be produced. Let v represent the velocity, x the height, s the specific gravity of water expressed in pounds, and h the number by which you must divide the square of the velocity, in order to find the resistance of the air; it is generally taken as equal to 500 lb.

"You have then three equations and three unknown quantities.

1st. $s \times v = r$, resistance of the air at the moment of equilibrium.

2nd. $\frac{v^2}{h} = r$

3rd. $v^2 = 64\,x$ taking 8 as the multiplier.

$\therefore\ h s^2 = 64\,x$, from which x the height at which the equilibrium between the accelerating and retarding forces exists, would be found. As might be expected this number would be very great. The above equations are also useful in finding the velocity due to any given height when the water flows *directly* into the air, but in the case of the hydraulic railway, where the vertical pipe deflects into one horizontal, the velocity of the water issuing from the vertical pipe will be gradually diminished, in consequence of the friction of the *horizontal* pipe, and therefore the velocity of the *whole* column (as will be seen) will be reduced to that of the water issuing from the extremity of the horizontal pipe.

I shall next proceed to show that cohesion does not account for the uniform flow of the whole column so simply, and consequently not so well, as the pressure of the atmosphere on the surface of the water. For suppose that in some part of the passage of the water through the pipe, two consecutive portions separated, a vacuum would be formed between them, consequently the atmosphere would act as an accelerating force on the upper portion, and as a retarding force on the lower portion, and evidently would cause the junction of the two parts—the vacuum then ceasing, the whole column would move together. A familiar illustration of this explanation is afforded by the well-known experiment of half-a-crown, and a piece of paper of the same form placed at the back, falling together to the ground. It is not the action of gravity alone which makes them fall together, but the pressure of the atmosphere on the half-a-crown. It is, I believe, clear, if these results be correctly deduced from sound principles, that cohesion does not satisfactorily explain the uniform flow of the column of water, and certainly does not reduce the velocity by one half, and consequently demonstrates the errors of the fifth paragraph, alluded to at the commencement of this letter. Some curious results, explaining the uniform flow of the column, even in the case of the atmosphere not acting on the surface of the water, might be deduced from the above equations, by differentiating them.

"You would oblige me by inserting this letter.

"I remain, Sir,

"Your obedient servant,

"T. F——x."

Before we reply to the two points to which our correspondent particularly directs attention, we must correct a misapprehension he appears to have, respecting the statement of the diminution of velocity by increase of aperture. What we stated was, "that if the size of the aperture *approximate to that of the pipe*, the velocity will be diminished, and that if the aperture be of the same size as the pipe, so that the *whole column* must fall as rapidly as the issuing fluid, the velocity will be diminished one half, without making allowance for friction."

We never intended to assert, as our correspondent appears to imagine, that the velocity of water through a small aperture would be greater than through a large one, unless the aperture be increased so much as to bear a sensible proportion to the size of the containing vessel.

We shall reverse the order in which our correspondent has considered the subject, and direct attention in the first instance to the cause of the continuously equal flow of water down a vertical pipe, because the main question rests on the admitted uniform flow of the fluid. The initial and the final velocities being the same, there must, as we contend, be a deviation in this case from the usual law that regulates the velocities of falling bodies. With respect to the cause of this equal fall of water, the difference between us is rather a difference in form than in substance. Our correspondent admits that the flow is uniform, but he attributes it entirely to the pressure of the atmosphere; we attribute its immediate cause to the cohesion of the particles of the fluid, without which, the pressure of the atmosphere could have no effect. Were it not for the coherence of the particles of the water, they would immediately separate in falling, and the particles would fall independently and with different degrees of velocity. Their coherence prevents this. Each particle of water in the pipe coheres to the particle immediately above it, with sufficient force to overcome the minutely different degrees of gravitating momentum, due to the difference in their respective times of falling. The effect of this continuity of coherence, transmitted from particle to particle, is to form a running *rope of water* in the pipe. This rope of water, if we may be allowed the expression, being supposed of equal size throughout, must have an equal velocity in every part of its course; for as water is practically incompressible, a motion communicated to one part of the fluid in the pipe will be communicated to all other parts as effectually as if it were a solid moveable column. It is true that the pressure of the atmosphere tends materially to prevent the separation of the water flowing down a vertical pipe, in the manner stated by our correspondent; but were it not for the coherence of the fluid particles, the pressure of the atmosphere would have no effect. Small round shot, for example, would not fall down a vertical pipe in a continuous stream, but in separate particles, and with differing velocities. The experiment of the half-crown and piece of paper, adduced by our correspondent as an illustration of his explanation, is not, we conceive, applicable to the purpose. It is not the pressure of the atmosphere on the paper that causes it to fall in the same time as the half-crown, for it is well known, that in a vacuum, even a feather will fall to the ground as soon as a guinea. The cause of the paper falling through the air in the same time as the half-crown, must be attributed not to the pressure of the atmosphere, but to the avoidance of resistance from the air, in consequence of the paper following closely *in the wake* of the half-crown, which sustains all the resistance.

It will be a curious, and we believe a new point, to ascertain to what extent atmospheric pressure influences the flow of water down vertical pipes. Many of our readers may have noticed the force with which water in a reservoir is drawn into the orifice of a long vertical pipe as the fluid flows down. This force results from the weight of water in the pipe, and from the pressure of the atmosphere on the surface of the water in the reservoir; the one tending to separate the cohering column of fluid, and to produce a vacuum, the other pressing in the water to counteract this effort. If the hand be held on the orifice it is pressed against the aperture with a force corresponding, within certain limits, to the height of water in the pipe. Were the length of the pipe greater than 33 feet, so that the weight of water surpassed the pressure of the atmosphere, a Torricellian vacuum would be produced, between the surface of the water in the pipe and the hand, and the latter would be drawn, or forced, against the orifice with a pressure equal to that of the atmosphere. No additional length of pipe would then increase the pressure. The vacuous space between the hand and the water in the pipe would be increased, but the pressure would evidently remain the same. The inferences to be drawn from these premises, are—first, that the velocity of the flow increases with the length of the vertical pipe, until the column of water balances the pressure of the atmosphere; secondly, that when an equilibrium is established between the column of water and the pressure of the atmosphere, the maximum effect is produced, and no additional length of pipe will add to the velocity of the flow from the reservoir.

Having thus disposed of the first objection raised by our correspondent, we shall proceed to consider the point on which we more essentially differ. Our position is, that the velocity with which water issues from a vertical pipe is half the final velocity due to the height of the column. Our correspondent disputes this position; but instead of adducing arguments to prove that it is an "important error," he takes for granted the very question in dispute, and thereupon founds a formula for determining another question, with which the present has no immediate connexion. We affirmed, that the velocity of water flowing through vertical pipes differs from the velocity of water issuing from an orifice, in the bottom of a large column of equal height; we stated, also, the cause of this difference, and its amount. Our correspondent, by way of refuting this opinion, *assumes that there is no difference;* and then proceeds, on the ordinary data for calculating the velocities of falling bodies, to estimate the height from which a body must fall, before an equilibrium is established between the accelerating force of gravitation and the resistance of the air. We shall not imitate this summary process of disposing of the subject in dispute, but shall endeavour to show that, according to the generally recognized laws of motion, the velocity of water issuing from a long vertical pipe, cannot be the velocity which is due to the height; and we shall then show the cause of this apparent deviation from the usual law.

In the first place, it must be borne in mind, that it is admitted, that a pipe having the same diameter throughout, continues full during the flow of water through it; therefore, as water is incompressible, the velocity of the water must be the same at the top of the pipe as at the bottom. Suppose the pipe to be 16 feet vertical, and to be covered with water just sufficiently to keep it constantly full. Then, as the velocity due to a height of 16 ft. is, in round numbers, 32 ft. per second, if the water issue from the pipe with that velocity, the same velocity must be communicated to the fluid in all parts of the pipe, as it forms part of the hypothesis that the velocity is uniform. We should, therefore, be obliged to assume the existence of some force, which could communicate to the water flowing into a tube from a state of rest, a velocity equal to that it would acquire after falling freely through 16 ft. It can scarcely be asserted, that the pressure of the atmosphere would communicate this additional velocity, for the upward pressure on the fluid at the bottom of the pipe must always counterbalance the downward pressure on the top; and were the pipe a very long one, the upward pressure would be the greater, owing to the increasing density of air at lower elevations. There is, indeed, no rationally conceivable force called into action but gravitation; and if the whole column of water instantly acquire a velocity, which is due only to a fall through its whole length, the force of gravitation must, in some unaccountable manner, be doubled; for the momentum of a column of water, moving with a uniform velocity of 32 feet per second, is equal to the mean momentum of the same weight, were its motion to increase progressively from a state of rest to a velocity of 64 feet. There is not, however, the slightest ground for assuming that the force of gravitation produces any such effect. The final velocity of a body falling freely through 16 feet is, within a fraction, 32 feet per second, the mean velocity of the fall will therefore be one half, or 16 feet per second; and that, we contend, is the velocity with which a continuous and equal column of water would fall through a vertical pipe 16 feet long; putting out of consideration the friction of the pipe and the resistance of the air. In the case of water issuing through an orifice, the velocity due to a height of 16 feet is 32 feet per second, when the areas of the column and of the orifice are greatly disproportioned; but it appears from the preceding reasoning, that *the whole column* of fluid would issue with only half that velocity, which was the point to be proved.

Having, therefore, shown that the conclusion at which we have arrived may be deduced as a necessary consequence of the continuous uniform flow of water in vertical pipes, we shall next proceed to consider the conditions of water when flowing down vertical pipes, and when issuing from an orifice; and we shall endeavour to arrive at the same conclusion by a different process of reasoning.

It was demonstrated by Daniel Bernoulli, that the impulse of a "vein" of fluid falling perpendicularly, is equal to the weight of a column whose base is the area of the vein, and whose height is twice the fall producing the velocity. For example; if v be taken as the final velocity of the efflux acquired by falling freely from a height h, then it is well known that a body falling with the final velocity, during the time of the fall, will pass through a space equal to $2\,h$, or twice the height. As the water commences and continues to flow through an orifice with the final velocity due to the height, the quantity of water falling through the aperture in a given time is double the quantity that would flow through it if the flow commenced with the initial velocity of a falling body, and progressively increased to its final velocity.

Bernoulli's hypothetical vein of fluid was without any tangible boundaries, and the particles of the fluid in the vein were supposed to be pressed against, and changing places with, all the other particles in the containing vessel. It is this transmission of the pressure through the fluid, that causes the difference between the imaginary vein of fluid and a real pipe passing from the orifice to the surface. When the communication between the orifice and all other parts of the vessel is free, the water near the orifice is forced out, not only by the weight of the particles immediately above it, but all the particles of fluid are pressing towards the aperture and contributing towards the effect. The space occupied by the particles of fluid forced through the aperture, is immediately filled by other particles sustaining equal pressure. The continuity and equality of the pressure are thus preserved, which consequently maintains an equal and continuous flow, the height of the fluid being supposed constant. The velocity at the first moment of efflux is the same as would be acquired by a body falling freely from the surface, because the whole gravitating effects of the perpendicular vein of fluid instantly act on the portion of water above the orifice, and this action is continued, because the pressure remains free and constant. When a vertical pipe passes from the orifice to the surface of the water, so as to exclude the action of the surrounding fluid, the conditions are essentially changed. Suppose such a pipe to be filled with water, the base of the vein of water within, *when at rest,* would sustain the same pressure as another equal area on the bottom of the vessel, the heights being equal. But as the force then acting on the lowest lamina of the fluid is produced solely by the pressure of the laminæ of fluid above, were the lowest one to separate from the upper by the impulse of this pressure, the force would instantly cease, for the lamina immediately above the lowest not being impelled with equal force, would not have the same velocity. The adhesion of the particles of water would, however, prevent the falling vein of fluid from being divided, because the difference of the force acting on one minute lamina, and that acting on the fluid particles immediately above, would not equal the cohesive attraction which holds them together. The vein of fluid would, therefore, cohere and fall through the vertical length of pipe as a solid mass. Again; as the upper part of the vertical vein of fluid in the pipe would be as free to move under the influence of gravitation, when the supporting base was removed, as the lower portions of the vein, and as the force would be exerted in the same time, the velocities they would respectively acquire, would be the same; and they would fall through equal spaces in equal times. The length of pipe we have assumed to be 16 feet, therefore, it would be emptied by the fall of water in one second, the final velocity on issuing from the pipe would be 32 feet per second, and the mean of the initial and final velocities would be 16 feet per second.

If we suppose the water just to cover the top of the pipe, so as to keep it constantly full, the flow of water would then, it is admitted, be uniform instead of being accelerated, as in the preceding illustration. The water at the lower portion of the pipe would be retarded in its fall, by the continuity of cohesion between the particles of the fluid in the falling vein; or, in other words, the velocity due to the fall at the bottom of the pipe, would be diminished, and a greater velocity than is due to the fall, would be imparted to the fluid in the upper part of the pipe, to produce a mean velocity. The mean between the initial velocity and 32 is 16. Thus, in whatever mode the question is considered, we arrive at the same conclusion, that the velocity with which water issues from a vertical pipe, (not exceeding 33 feet in length,) is one-half the velocity due to the height of the column.

We trust we have proved, even to the satisfaction of our correspondent, that there are no errors in our reasoning on this subject; and that he was induced to think so, in one case by a misapprehension of our meaning, and in others by a hasty consideration of the main proposition: which appears, though in reality it does not, to deviate from the recognised laws of hydrodynamics. The theory of the flow of water through pipes well deserves a more full consideration than we have now time or space to bestow upon it, and to which we shall probably return.

JAMES NASMYTH'S PATENT DIRECT ACTION STEAM FORGE HAMMER.

The truly valuable qualities possessed by wrought iron as the material of all others the best adapted to withstand force, has rendered its use as a mechanical agent almost universal, so important are the purposes it serves in enabling man to combat with the elements, and as it were bend them to his will, that we may almost measure the progress of civilization in any nation by the quantity of that inestimable material they convert to their use; hence it is that Great Britain owes no small portion of her power, wealth, and mechanical supremacy to her superior knowledge of the use and capabilities of this the most serviceable of all substances.

National improvement is always indicated and accompanied by increased consumption (by reason of increased application) of wrought iron; by its use man first merges from the savage state, and by its extended employment the most civilized nations not only maintain, but advance in their improvement. It is, perhaps, unnecessary here to remark how entirely we are indebted to wrought iron for the services of the steam engine; and its innumerable progeny of happy results, to say nothing of railways and steam vessels, in the very hulls of which, as well as in other ships, it is rapidly manifesting its superiority over wood, and so giving to the world another magnificent evidence of its all but universality of application. Hence it is that few mechanical improvements are of more real importance than those which relate to the manufacture of wrought iron, not only in respect to its production in the first instance, but also to our increased facilities, and means of working it into such forms as may be rendered desirable and necessary.

By a property almost peculiar to wrought iron, namely its all but unmeltableness, its applications would have been very limited, by reason of the difficulty we should have experienced in fashioning it into any required form, but by another peculiarity, namely its capability of being welded, we have the loss of convenience arising from its unmeltableness *more* than made up to us, and where we add to this its extreme malleability, by which property and by the assistance of heat, it is capable of being forged into any required form, our command over it is only limited by our means of applying the requisite force, whether by compression, as in the case of the process of rolling, or by blows, as in the case of forging by the hammer; this latter process being by far the most important, not only in respect to its affording us the means of giving to masses of wrought iron the requisite shape and form, but also, when the process of hammering is carried on with due energy, *while the iron is at a welding heat*, the effect of such hammering is productive of a most important improvement in the quality of the iron, as regards its tenacity and consequent capability of resisting strains without the risk of fracture, this gain of strength arising from the more intimate contact or union brought about between the particles of the iron, by reason of the more perfect expulsion of all those impurities which otherwise, by separating the particles or fibres of the iron, so impair its strength. Hence we have one of the many important reasons why it is so desirable that we should have the means of hammering iron when at the proper welding heat, *with all due energy*, whatever be the size or form of the mass in question.

The great success which has attended the application of the steam engine in the case of steam ships, and in other instances, has produced a demand for enormous forgings of wrought iron, such as paddle shafts, cranks, &c. that no small difficulty is now felt in the execution of large parts of them, having attained to such a magnitude as to be all but beyond the power and capability of the largest forge hammers to execute them.

The approach of this point of ultimate capability has long been felt, not only by the vast difficulty and expence by the ordinary means, such enormous forgings being so frequently attended by the destruction of the machinery employed, but also by the frequent occurrence of unsoundness being the certain result of inadequate means, and the exceeding the limits and capabilities of the machinery hitherto employed for the purpose, arising from a defect inherent in the principle on which such machinery has been constructed, the evils of which have been rendered more and more apparent by every successive attempt to enlarge the apparatus, with a view to endeavour to enable it to cope with the increase in the magnitude of the forgings it was required to execute.

It was with the view to remove *those defects in the principle* on which such forge hammers were constructed, and to produce such a hammer as should, in the most simple manner, attain all that was desirable in our means of forging the very largest class of work, and that in a manner infinitely more convenient, perfect, and economical, that led me to contrive my *direct action steam hammer*, which I shall now proceed to describe, and which has realized my most sanguine expectations of its advantages.

In order to give such of my readers as are not minutely acquainted with the subject, a more clear view of the advantages possessed by this direct action steam hammer over those of forge hammers of the ordinary construction, I must refer them to Fig. 1, which is intended to represent a forge hammer of the largest class, and generally arranged according to the most improved principle. According to the scale on which this sketch is made out, such a hammer would be fully what is called a seven ton hammer, and consequently adapted (so far as its principles of construction will permit) for the execution of the largest class of work.

One chief and universal feature in all such hammers, is, that the power which causes them to rise and fall, and so give out blows on the work on the anvil, consists of *rotary motion*, which originating in the *rectilinear* motion of the piston of the steam engine, is conveyed to the hammer by and through the medium of *revolving shafts*, wheels, &c., and finally reconverted into its original up and down motion by means of the cam wheel, marked D in the sketch; thus, by a very *roundabout* course we have brought our power back again into the form it first existed, namely, rectilinear motion, or as nearly so as the radial action of the hammer will permit. And what advantage have we obtained by causing our power to travel to its object by such a roundabout course? none that I ever could see; and as to the disadvantages, they are many and most serious. In the first place, there is great loss of power, on account of the very unfavourable manner in which the momentum of the fly-wheel on the cam shaft D communicates its motion to the helve of the hammer, by a jolting action most unfavourable to the economical communication of power; add to which the vast space of the forge shop, occupied by all the intermediate apparatus of a *complete* steam engine, with its requisite fly-wheels, shafts, beams, and *very costly foundations*, which, in order to endeavour to maintain the apparatus in due order, has to be made of more than ordinary substantiality; so much so that, to resist the destructive effect of the vibration given to the entire machinery by the action of the hammer, the foundations have to be made so solid

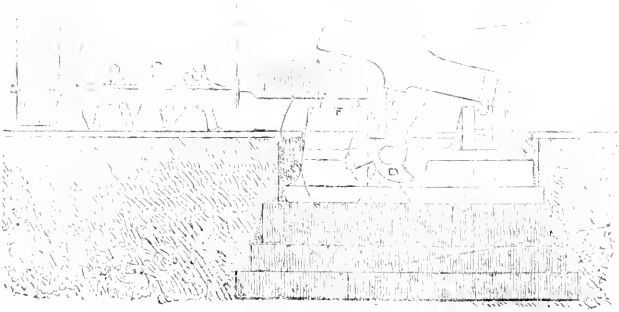


Fig. 1.—View of the Old Tilting Hammer.

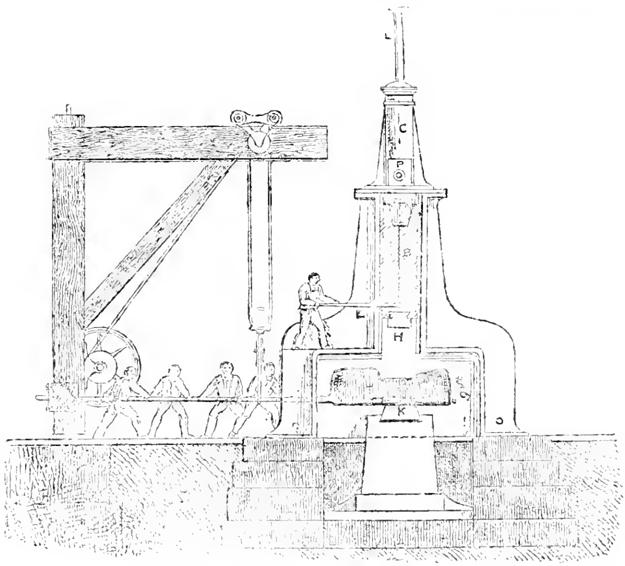

Fig. 2.—Nasmyth's Direct Action Steam Hammer.

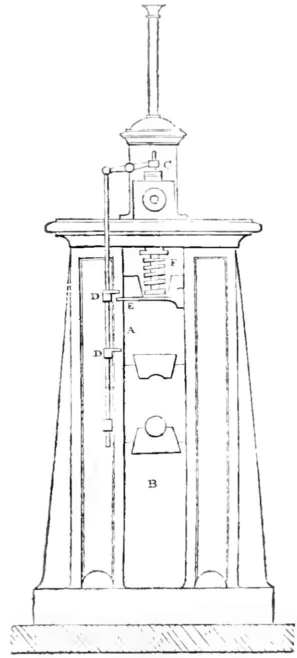

Fig. 5.—Self-acting.

as to cost, in some cases, nearly as much as the whole metallic part of the apparatus.

With respect to the action of such a forge hammer, as seen in Fig. 1, it will be found that one grand defect in principle exists, namely, that when engaged in hammering a large piece of work, as that seen in the sketch, by reason of the work occupying the greater part of the clear space between the anvil face and that of the hammer, we have thereby a slight blow when we are doing a large piece of work, and a heavy blow when we are hammering a small or thinner piece of work, which is just the very reverse of what we could desire. And in the execution of large work this is found to be a most serious evil, in as much as, from the nature of the case, we would wish to have the most powerful and energetic blows that it is possible to command. The result of this is, that neither is the mass rendered so sound as we could desire, nor is it brought to its required form except by repeated heatings, at the very great sacrifice of time and iron, in so far as, ere the limited blows of the hammer have produced the required change of form, the welding heat has gone off, and all blows after this tend rather to loosen than compact or solidify the mass. Again, we have another very serious evil, namely, the very confined limits of the space between the hammer face at its highest, and that of the face of the anvil, which renders it quite incapable of admitting or operating upon a mass of any great breadth or height; and besides having the machinery of the hammer quite in the way, in many cases we have also this other disadvantage, namely, that except for one thickness of work, the hammer face and anvil are not parallel, as will be evident on referring to the sketch, and considering that the face of the hammer acts radial to the centre, S, Fig. 1, in which it rocks. This evil is to a small extent obviated, by means being given to raise up the tail or centre, S, but this process is not only difficult, but can only be done between the heats.

With a view to relieve all these defects, I have contrived my direct action steam hammer, which is represented in one of its many forms and applications in Fig. 2.

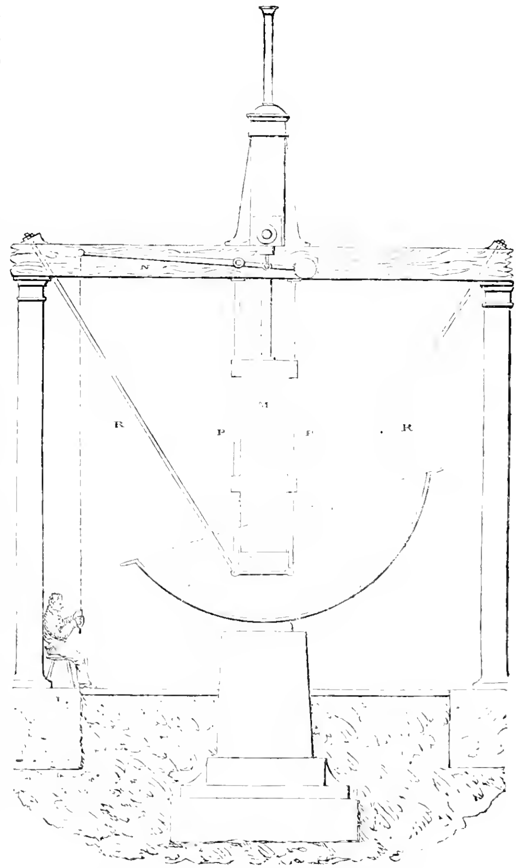
It consists simply of a cylinder C turned as it were upside down; that is, its piston rod comes out at the bottom of the cylinder instead of (as in most cases) out of the top; this cylinder is supported over the anvil K by two upright standards, O O, the end of the piston rod being attached to a block or mass of cast iron, B, guided in its descent by planed guides or ribs cast on the edge of each standard. This block of cast iron is the hammer or blow-giving part of the apparatus, while the cylinder, with its piston and piston rod, supplies in the most simple, straightforward, and direct manner, the power by which the striking block B is lifted, or raised up. *Gravity* performs the downward action for us in a most *direct* manner. In order to set this steam hammer in action, steam of such a pressure as, operating upon the underside of the piston, will a little [1] more than balance the weight of the block B, is conveyed from a suitable boiler, (situated in any convenient part of the premises,) through the pipe P into the valve box, in which a slide valve of the most simple form works. The valve being up, permits the steam to press upon the underside of the piston, and up goes the block B *to any height* (within the limits of the length of the cylinder) which the forge man may require. The handle E is now moved in the contrary direction, which not only prevents any further admission of steam, but also permits that which had entered, to escape by the pipe L; the instant this is done, the block B descends with all the energy and force due to its weight and the height through which it falls, and discharges *its full and entire* momentum upon the work then on the anvil, with such tremendous effect, as to set the blows of all previous hammers at utter defiance! In fact, the power of such a hammer is only limited by the size we please to make it, as *the principle* is capable of being carried out to any extent; whereas, in the case of such hammers as in Fig. 1, they have their limits, by reason of the very mass of material causing them to be weak *per se*, by the intestinal contraction of the iron which composes their mass, and which in their action is so destructive and trying to such a form; the consequence is they generally break over just behind the neck.

I have only alluded to the means which this steam hammer gives of obtaining tremendous blows. But energetic and powerful as it is, it is at the same time one of the most striking examples of the manageability of the power of steam; inasmuch as, when we desire to have *any variety* in the intensity of the blow, varying from the most gentle *nut*-cracking tap! to the most awful smash, we have simply to work the valve handle in proportion, and by so regulating the *exit* of the steam we can let down the block, like closing a well hung window, or *arrest its downward progress in an instant at any part of its stroke*, and retain it there at any required height at any required time; on the other hand, by duly regulating the entrance of the steam, we can lift the block to any required height, from the face of the anvil or surface of the work, and so regulate the amount or rapidity of the blows accordingly.

The form and arrangement of the steam hammer, as given in Fig. 2, is such as present experience shows to be most convenient, according to the scale on which the sketch is made out, the distance between the standards O O gives a clear space of 12 feet, namely, six feet on each side of the centre of the anvil, and six feet height clear over head, as figured in the sketch. But these proportions may of course be varied at will, as the *principle* of this steam hammer affords every facility to extention or otherwise. The space on each side of the anvil, in front and behind, being quite clear of all machinery, gives every facility to the introduction and management of the work, when we progress, as will be evident and fully appreciated by practical men.

The comparatively small space which the entire apparatus of the steam hammer occupies, may be judged of by a glance at the sketch, Fig. 2, as compared with that of the ordinary construction in Fig. I. Had I turned the standards in the sketch, Fig. 2, so as to give a *side* or edge view, the contrast in respect to space occupied would have been much more striking. As regards the comparative original cost, any one the least accustomed to such matters will at once see the vast advantage in that respect in favour of the steam hammer, to say nothing of its vast superiority as to efficiency and little liability to derangement; in fact, so simple is it, that there is scarcely anything to go wrong. One great source of its durability in this respect is the manner in which the mass of the block is raised, namely, through the medium of *the* most elastic of all bodies—steam; which, in place of

Fig. 4.



any destructive jerk, as in the case of motion conveyed by impulse through solid media, so apparent and destructive in its effect in the case of the apparatus of the ordinary forge hammer, with the steam hammer the lifting motion is performed so smoothly as to be absolutely silent in its action, as if the great block had forgot, for the while, that it had any weight at all. I do not intend here to rival the celebrated Caterfelto by wondering at my own wonders! but truly the action of this simple but most powerful machine, is not a little striking, both in its action as well as effect. I think experience will prove that I am not too far yielding to sanguine expectations when I state, that the vast facilities which this invention gives to the treatment of large masses of wrought iron, will introduce quite a new era in the manufacture and working of wrought iron. We have now, by means of this steam hammer, a power and capability of producing forgings of wrought iron of *any* dimensions, whose soundness will give the best evidence of the value of the invention in that respect, and from the vast facilities of executing the most ponderous and acquired forms the saving of time and finish which can be attained under such a hammer will also prove that a great step has been made in the mechanical arts. In conclusion, it may perhaps be as well to remark on the valuable and important influence which such

[1] About five to six per cent more pressure than will just balance the block gives all due activity to the upward or lifting action of the block.

a hammer will have upon the quality of iron, as in the case of boiler plates and such like, the quality of which, as regards *soundness*, entirely depends on the efficient manner in which they have been hammered and consolidated in the primary process of faggoting or shingling, namely, the forming into one perfectly *solid* mass, the block of iron from which such boiler plates, &c. are rolled. Nine tenths of the defects which are met with in boiler plates, and which have caused such disastrous results, namely, defects from blisters, have arisen or may be traced to imperfect consolidation resulting from inadequate means of hammering the original mass into a truly solid block, by our having the *power* to force out all the scoria, which, otherwise lodging between the pile of pieces of which the faggot is composed, gives rise to the most serious defects, which every practical man has had to deplore. It will, in like manner, be scarcely requisite that I state any of the advantages that will arise in our having, by means of the energetic action of the steam hammer, a perfect security against unsound *anchors*, the importance of which requires no words to set forth. In short, we have now at command an almost new power, inasmuch as, by means of this steam hammer, we have an accession to our means of dealing with power in the form and state of *percussion*, such as has never been attained before, and that in the most *simple*, straightforward, and *effective* manner.

Fig. 3 shows the application of the hammer A for forging an iron shaft laid over the anvil or block B, and is made self-acting, as will be seen by a reference to the cut, that when the tappets D D come in contact with the pin or spring on the block E, the steam valve C is opened or closed.

Fig. 4 shows the application of the steam hammer for coppers, pans, &c. The hammer M works in the guides P P, suspended by the rods R to the beam above, like an inverted truss: the action of the man pulling down the lever N opens the valve, so as to admit the steam for raising the piston and with it the hammer.

I may remark, that one boiler can be made to work any number of steam hammers, as the steam has only to be conducted to each by pipes, and the power let on and shut off in the same manner as gas; and in most iron forges, the waste heat of the furnace will more than furnish the requisite steam. There are many other applications and details connected with this important invention, but reluctance to further trespass on your readers' attention, and the space of your columns, causes me to defer to a future opportunity.

But I trust the high importance of the subject will plead my excuse for the length I have allowed my remarks to extend to.

With most sincere respect,
I am, very truly yours,
JAMES NASMYTH.

OBSTRUCTION TO WINDOWS.

SIR—Your Old Subscriber at West Derby does not, I think, quite understand the nature of a right gained by prescription to a window overlooking a neighbours' land. In the case put by him, the right is not, as I conceive, so much to the *window* as to an *easement of light and air* through the window, and consequently "much (query, all) must depend upon the hard swearing of witnesses on both sides, as to whether a building erected near a window does or does not obstruct the light and free circulation of air." Indeed I doubt very much whether proof that a building had been erected within two feet of the window would be proper evidence to rely upon, unless it were also proved that the said building had prevented a certain quantity of light and air from finding its way to the window. With regard to question 3, it is obvious that the right being to *light and air*, and not to *space*, a building may be erected as high as the *upper side* (beyond the limits of the building act) of the window sill, it being impossible that such an erection should obstruct the free passage of either to the window.

6th January, 1843.

I am, Sir,
Yours very obediently,
R. R. A.

ON THE SEWERS OF THE METROPOLIS.

1. *Report to the Secretary of State from the Poor Law Commissioners on an Inquiry into the Sanitary Condition of the Labouring Population of Great Britain.*

2. *Address on the above Report in reference to those parts which inculpate the Metropolitan Commissioners of Sewers, delivered at a Meeting of the Court of Sewers for Westminster, &c.* By the Chairman, THOMAS LEVERTON DONALDSON, Esq.

WE are heartily glad that the subject of the sewers of the metropolis is likely to become an object of inquiry by the administrative authorities, a course for which we have long been anxious. In consequence of a voluminous report by Mr. Chadwick, the secretary of the Poor Law Commissioners, containing many very stringent remarks on the drainage of the metropolis, the ire of many of the functionaries has been excited. It is very evident that there must be something radically wrong in the management, when we find such vast sums of money yearly raised in the metropolis under the name of sewer rates, while the extension of sewage is so very slow. It will be our endeavour to show, without entering upon all the points in dispute, that the present laws and system of building sewers are most oppressive and expensive to builders, and consequently the important system of draining house by sewers is avoided, and instead thereof, cesspools are resorted to, and every scheme which can be thought of to save the expense of building a sewer. Under such circumstances, we are sorry that Mr. Donaldson, for whom we have great respect, should have betrayed himself so far as to become the champion of the present system. The report of Mr. Chadwick, indeed, like the apple of discord, seems to have been productive of much asperity and bitterness of feeling.

Our present object will be to prove that some broad and general measure must be at once adopted for the regulation of the sewage of the metropolis, and that all petty legislation on the subject of drainage should be suspended. We must not have the metropolis split into half a dozen commissions. Now that the subject is fairly opened, we do sincerely hope that the Secretary of State will not listen to the resolution passed at the court of commissioners for Westminster sewers on the 13th ultimo.

"That the Court requests an investigation under the authority of Her Majesty's Secretary of State for the Home Department into the charges brought against the Westminster Commissions of Sewers in the report of the Poor Law Commissioners on the sanitary condition of the poorer classes, and to ascertain the best means of cleansing the streets and roads by aid of sewers, and also the most advantageous form of sewers for the public interests."

This is giving the real matter at issue the go by, we want not the isolated works of the Westminster Commissioners, but what we do want is an examination into all the metropolitan commissioners, to see whether they cannot be advantageously consolidated into one body. We have now on the northern side of the river Thames, the City, the Westminster, the Holborn and Finsbury, the Regent Street, the Tower Hamlets, and the Stebon Heath Commissions; here we have six different commissions, and it is consequently impossible to lay down any one system of drainage for the whole metropolis: for to do so it is requisite to have the consent of all the different commissions, which would require months to obtain, even supposing it possible that they should all agree. We have running right through the very centre of the Westminster sewage, a sewer of a large class, and at considerable depth, constructed about 25 to 30 years since, belonging to the crown, and capable of draining an immense district; yet this sewer cannot be touched by the Westminster Commissioners; then again we have, as Mr. Donaldson tells us, in his report, the Westminster sewers running from the Thames up Tottenham Court Road, to the New Road, then the Holborn and Finsbury Sewage commences, and after the sewer passes through the latter district, it comes to the county drainage, so that any improvement in the drainage of the up-lands of the county could not be made without first, the Westminster Commissioners constructing a new sewer, or lowering an old one, then the Holborn and Finsbury doing the same. So, also, if either commissions wished to divert the upland waters, by constructing catch water drains, so as to prevent too great a flow down any particular district, and prevent the lower parts of the metropolis from being inundated, it cannot be done, and the consequence is, that each commission is obliged to cut about and alter the old sewers, to get rid of the evil in the best way they can.

Mr. Donaldson tells us that

"During the present century, and particularly since the removal of old London Bridge, every opportunity has been taken to lower the outlets. For instance, the Essex Street sewer, between 1816 and 1836, has been lowered from its outfall at the Thames to near Great Russell Street. Bloomsbury, in length 5,800 feet. The eastern branch of the Hartshorn Lane Sewer, between 1831 and 1839, from Long Acre to the New Road, by the line of Tottenham Court Road, &c., in length 4,200 feet. Another branch of the Hartshorn Lane sewer, between 1820 and 1837, from the south end of the Haymarket to Oxford Street, by the line of Princes Street, Wardour Street. &c., in length 3400 feet. The whole of the King Street sewer, between 1830 and 1832, from Westminster Bridge to St. James's Park, 1200 feet. The Wood Street sewer, between 1824 and 1827, the College Street sewer, between 1824 and 1832, and the Romney Row or Horseferry Road sewers, in 1840, have been lowered and rebuilt of enlarged dimensions from their outlets for their whole extent, being a length of 6850 feet, presenting in these lines alone a total of *only* 21,450 feet."

Here, then, we have a fearful summary of expenses incurred in *lowering* the old sewage only, and we think an inquiry might be usefully directed to see if all the commissions had been united, whether it would not have been far cheaper and more effective to run new lines of sewer from the river Thames through districts which had no sewers and to have joined the old sewage at some distant point, and thereby have relieved the old sewers in the lower levels.

By this arrangement, we should have had the old sewers still remaining, which might have answered the purposes of draining either high or low lands, and have obtained an immense additional length of new sewerage at the same expense. We do not mean to say that in all cases under the present system of separate commissions, this could have been effected; but it is a fair subject for enquiry, and can only be got at, by having a thorough examination of all the plans and levels of the present sewerage, in every district, connected with the metropolis.

Mr. Donaldson subsequently calls our attention to the vast works that have been executed for the improvement of the King's Scholar's Pond Sewer; let us give his own words.

"But the greatest work ever executed by this or any other commission has been that effected on the *King's Scholar Pond Sewer*, which has been wholly rebuilt for an extent of upwards of three miles, from the River Side to the Regent's Park within the last 24 years. It has been so vastly deepened and enlarged since the year 1816, that property of the most valuable description, in the neighbourhood of the sewer, at Pimlico, including Buckingham Palace, the lower floors of which are below the highest tide level, and most of the streets adjacent to the sewer between Piccadilly and the Regent's Park, have been benefitted to an incalculable extent. Formerly the whole neighbourhood was inundated by every sudden fall of rain, so that many of the houses in Berkeley Square, Bruton Street, Avery Row, South Molton Street, Wigmore Street, South Street, Baker Street, and Spring Street, were greatly depreciated in value; and some houses in Berkeley Street and Bruton Street remained unoccupied for many months together, in consequence of the well-known fact, that in the summer months those premises were subject to have their lower floors burst up during thunder storms, and the water to rise so as to extinguish the kitchen fires, &c.

"One of the great means for remedying these evils was designed and carried into effect by Mr. Dowley. I especially allude to the entire removal of two immense stone piers, which had at some former time been built in the water way of the sewer, and which piers supported certain parts of the heavy and lofty walls of the houses in Grafton Street, St. George's. These piers, one measuring 53 feet in length, the other of a more square form, whereby the water way was divided into two channels, were formerly considered advantageous to the property lower down the line of sewer, by penning back the torrent of water in times of storms. The work of taking out these obstructions as also removing two great projections, and putting in an inverted arch throughout the whole length of sewer between Hay Hill and Bruton Street, in length 550 feet, at a greatly increased depth, was performed from within-side the sewer, which had its course under buildings. These works proved of such vast importance to the sewage of the district, that what was formerly reported to be impracticable by several eminent engineers, amongst whom were the late Mr. John Rennie, Mr. Jessop, Mr. Chapman, Mr. Bevan of Leighton Buzzard, and others, was actually and substantially carried out, and was afterwards inspected by some of these gentlemen, as also by a numerous committee of the commissioners, who not only approved of the work that had been so done, unseen by any one other than by the workmen employed, but were somewhat surprised that so bold an attempt had been successfully accomplished.

"In the prosecution of the operations necessary for reconstructing *this one line of sewer*, various instances may be cited to show that, at all events, the management and execution were entrusted to an officer of this court who knew something of his profession, and to any one, who is acquainted with that part of the district lying between Piccadilly and Oxford Street, it must be manifest, that cases requiring ability, foresight, science and practical experience frequently arose. I mean such difficult cases as passing a sewer seven feet six inches wide in the clear with side walls two bricks thick, at a depth of 22 feet and upwards, along White Horse Street, Piccadilly, a street only 20 feet wide. Again, carrying the same sewer through Sun Court, Curzon Street, which is less in width than that of the external dimensions of the sewer itself. And, further on, this sewer winds its course under and close to buildings of great magnitude, nearly the whole way from the lower end of Berkeley Square to Oxford Street and in most instances at a depth of from 10 to 12 feet *below the foundations of the contiguous buildings*. Surely, these were works, which, by their nature and extent might be considered of a scientific and high order of civil engineering, and such as have only been approached by some recent works, perhaps, of the city commission of sewers."

With all due deference to the talents of Mr. Donaldson, we are inclined to doubt the latter part of his statement, that these works "might be considered of a scientific and high order of civil engineering." Instead of enlarging this sewer, and rebuilding it, with all its original sinuosity, the course we should have preferred, would have been to have run a new sewer from where the Scholar's Pond sewer crosses in Oxford Street, near South Molton Street, along Oxford Street, and united it with the Regent Street sewer belonging to the crown. No doubt we shall be told, this could not be done, as the Westminster Commissioners have no power to enter the Regent Street sewer, this then would at once have proved the great necessity of uniting the several commissions; now, if this plan could have been adopted, it would have relieved the large pressure of water flowing down the sewer, and inundating the houses as represented in Mr. Donaldson's report, and would have saved the great expense incurred in removing the large piers under the houses in Grafton Street, and rebuilding the tortuous part of the sewer in the vicinity of Curzon Street; and another advantage gained, would have been in giving Oxford Street a sewer, which had none. Similar relief might have been given to other portions of the large sewers which were overpowered with the upland water, and new sewers given to such portions as had none before; for instance, another sewer might have been constructed, to have commenced about Berkeley Street, and run along Piccadilly, and discharged itself into the Regent Street sewer, near the Quadrant, connecting with it the sewers of the side streets, which would have relived the Scholar's Pond Sewer and have given Piccadilly a sewer which it was deficient of until lately. And again, the sewer of Pall Mall might have been diverted into the Regent Street sewer, although it comes to within a few yards of it the sewage is carried into the Scholar's Pond Sewer, and has to travel a distance of a mile and a half before it discharges itself into the Thames, whereas, if the former plan had been adopted, the discharge into the Thames would have been within half a mile. If these collateral sewers had been built, the vast sums of money in reconstructing a considerable portion of the Scholar's Pond Sewer, and building the large approaches described in Mr. Donaldson's address, might have been saved and part of the cost devoted to the new sewers we have described. We think that we could point out several other improvements that might have been adopted, if the commissions had been united; but we have already trespassed beyond our original intention upon this portion of the subject, and must now turn our attention to the more important part respecting the form, construction, and expense of the present sewers of the Westminster Holborn, and Finsbury, and Regent Street commissions.

We will first proceed to enquire into the present cost of constructing sewers, and see how far they might be modified, so as to induce builders of small tenements to construct sewers, in preference to cespools; in order to do this, we are at once brought to another bone of contention between the present combatants; one commission contends that the oval sewer is the best form, whilst another flatly contradicts it, and says that sewers with upright sides are the best; we must therefore first hear what Mr. Donaldson says upon the subject.

"With respect to the form of section of sewers, our commissioners have very wisely adhered to that, which experience has proved to them to be substantial and best calculated for the purpose. We are to recollect that under-ground constructions must be built so as to last for ages, otherwise a continued re-building of sewers causes a constant breaking up of the streets, and obstructions to thoroughfares, and a suspension to a certain degree of the commerce of the trades-people on the line. The sewers must be large enough not merely for the ordinary service of relieving soil drainage, but also for carrying off the torrents of water, which fall during violent storms. Hence a large capacity must be given them. Again, this large dimension is not without a further use in enabling the officers and workman to inspect and repair them with sufficient facility, the width even of our second sized sewers enabling two workmen to pass each other. As regards the upward sides of the sewer, it must be borne in mind that all circular work constructed of brick can only be formed by making the joints more open at the extrados than at the intrados, for the square shape of the brick does not lend itself to other than rectangular construction. Now these open joints are filled with mortar in a moist state, and before it is set, the earth to the depth of several feet is filled in, the centres are struck, and the consequence is an irregular settlement of the whole work; whereas with spreading footings, an invert at bottom, a circular arch at top, and upright side walls, most of these inconveniences are avoided, and the sewer, even if the earth be washed away at the top or sides, as sometimes happens from the bursting of one of the large main pipes of the water companies, stands upright and alone on its board base, whereas the oval sewer must have inevitably fallen over. I may also add two other important reasons for giving as much square construction as possible to the body of the sewer, and these are, greater security against imperfect workmanship, and detection of false thicknesses of work at sides. Besides, in the event of its being judged expedient to increase the depth of a sewer by putting in a new bottom by underpinning, this operation becomes comparatively easy with upright side walls—almost impracticable when they are curved. Much stress is laid in the report upon the curved side walls as materially aiding the rapidity of the current. But, in fact, the ordinary sewage *rarely rises above the invert*, and when it does, there is such a force in the volume of water, that no perceptible obstruction is offered by the absence of the complete circular form."

If, on comparing the sewers of the Westminster Commissioners, Fig. 1 and 2, with those of the Holborn and Finsbury Commissioners, Fig. 2 and 3, it must be seen that Mr. Donaldson's remarks about circular work are completely futile, for his objections apply equally to the arch and invert of the Westminster as they do to the Holborn and Finsbury; and as to the sides, the radiating of the courses in the oval form is so trifling, that it is not worth naming. And again, can Mr. Donaldson tell us if such an accident ever occurred, as the bursting of a main pipe, and of washing away the earth to the extent of endangering an oval sewer. We have frequently heard, that during the construction of the upright sewers, of their falling in [1], but never heard of such a case with the oval sewer. 20 years ago, we happen to have been engaged in the construction of about 1000 feet of sewage of the oval form, as shown in Fig. 5, built upon the crown lands in the vicinity of Regent's Park, and up to the present time we have never heard of a single failure, either during the construction or since; we think this fully justifies us in pronouncing that the oval form is most effective, and in point of expense infinitely to be preferred. Now let us compare the expense of both forms, we will take the cost of the materials and labour the same in both cases, 1s. per foot reduced, or 13*l*. 12*s*. per rod of brickwork, and 1s. per cubic yard for digging, strutting, and filling in or removing the surplus ground, the top of the sewer being taken as 6 feet below the surface of the ground.

Fig. 5,[2] the Regent Commission sewer is built in two half brick rims, and contains about the same quantity of brickwork as fig. 4, and may be taken at the same cost. Thus it will be seen that in adopting the oval form, there is a saving of 5s. 4*d*. per ft. in the first-class sewer, and 6s. 8*d*. per foot in the second-class sewer. Can there then be, after perusing the above calculations, a doubt as to which form of

[1] We could find several cases of the Westminster sewers falling in during their construction, and the upright sides bulging in, as at Notting Hill, and also in the vicinity of the King's Road, Chelsea. But we are told by the worthy chairman, that they were built by private individuals, and not by the commission. Let us ask Mr. Donaldson under whose direction and superintendance are they built? Dare a builder alter the form, or lay a brick contrary to the directions of the commissioners' surveyor; if this be the case, the commissioners are responsible for the work and the form of the sewer, and not the builder.

[2] We give the preference to the oval sewer, Fig. 5, over that of Fig. 4, as the larger part of the oval is downwards, which allows a greater flow of water to pass off quicker; we also consider that the extra half-brick thickness of the sides of Fig. 3, oval sewer, perfectly useless, and might with safety be omitted, which would reduce the cost of the sewer, 1s. 8*d*. per foot.

sewer the preference ought to be given? then why oppress the builder by compelling him to construct such expensive sewers as the Westminster Commissioners require? Why not, as we said before, give some encouragement? Nay, we would create every inducement to the builder of small tenements to construct sewers, and we feel assured that if the expense of building sewers could be reduced to 10s. per foot, making the charge for small houses of 15 feet frontage on *each side* of the sewer under FOUR POUNDS, that every builder would adopt sewers in preference to building cesspools, as the difference in expense would then be so trifling; but on behalf of the builder, we contend for a still smaller form of sewer than even the second size oval sewer, for in many cases where the distance required to be drained is not above 200 feet from a main sewer, with a good fall, we would allow an oval drain of half the altitude and breadth of fig. 5, to be constructed with a half-brick rim, or an 18 inch barrel drain, with manholes every 50 feet; the expense of such drains would be 2*l*. 5s. for houses on each side of the drain for the 18 inch barrel drain, and 1*l*. 10s. for the small oval form; this form of drain, is amply large enough for 25 to 30 small tenements, including the surface drainage; therefore, why put the builder of small tenements to the vast expense of erecting "second-size sewers, enabling two workmen to pass each other," when "the ordinary sewage rarely rises above the invert," for which the Westminster Commissioners charge 10s. per foot for houses on each side, or 7*l*. 10s. for a fourth-rate house.

We have dwelt more particularly upon sewers for small houses, as it is to these houses that a cheap form of sewage is wanted, for the expenses attending upon sewers, forming roads, paths, paying fees to district and paving surveyors, leases, and a variety of other incidental charges, which do not immediately belong to the construction of the house, fall almost equally the same on the small as on the large house, and raise the cost of the latter so enormously, that much higher rents are obliged to be obtained from the small tradesmen and operatives than would otherwise be required if these charges could be reduced. We could give an instance at the present moment, where parties who have built some fourth-rate houses immediately contiguous to a main sewer of the Westminster Commision, will not incur the expense of the sewage by paying 10s. per foot, but prefer constructing cesspools.

It will be a question well worthy of inquiry to ascertain what number of houses there are on each side of any of the sewers that have been built or rebuilt by the Westminster Commission, and see how many of those houses have taken advantage of the sewers. We are fearful the return would show very few. If this be the case, it will be the best proof that the enormity of the charge of 10s. per foot demanded by the commissioners, is of an oppressive nature, and if they continue to make this demand, we are fearful that very few houses in poor neighbourhoods will ever have drains to enter the sewers, and that all the calamities pictured in the report on the sanitary condition of the poor, will still rage with fearful violence. It is not for surface drainage that new sewers are so much wanted as to get rid of the nuisance of building cesspools under the basement, and in the close and confined yards at the backs of the small houses.

We cannot allow these observations to close, without offering a few remarks on the regulation for constructing drains. We believe all the Commissions compel each house to have separate drains, no matter how far the house may be from the centre of the sewer. We recollect, a few years since, seeing the ground opened to the distance of at least 60 feet long, and 10 feet deep, opposite to every house in the Grand Junction Road, Paddington. Now, if the commissioners would have allowed a 15-inch drain to have been constructed from the sewer for every three houses opposite the centre house, with a branch drain, nine inches clear, at the end next the houses, there would have been a saving of 100 feet run of digging and making good roads, and a drainage equally as effective, if not more so; for it is not so likely that the single 15 inch drain would have got choked as the three 9 inch drains. And again, why not allow a 12 inch drain to be constructed opposite the party wall, between two houses, for the drainage of the two, some compulsory law might be made for compelling both owners, if there should be two, to contribute their share to the repair or cleansing the drain, if it were required. By some modification of this nature, a vast expense would be saved both to builders and owners of houses, as the principal expense in carrying a drain into the sewer is generally the opening of the ground and making good the roadway.

We have, in the present notice carefully abstained from entering into an examination of the Flushing apparatus, the feasibility of cleansing the streets by means of the sewers, and also the consideration of uniting the paving of the metropolis with the sewers under one commission, the same as is now done in the City of London, for all these points require to be gone into at considerable length at some future opportunity. We hope we have been successful in establishing that sewers may be constructed far more economically, and equally as effective, as the present form of the Westminster sewers, and that considerable improvements might have been adopted in rebuilding and relieving the old sewage, and at the same time increased to a large extent the sewage, without any additional expense, and if we have done so, satisfactorily, it then behoves us to press upon the government to take up the inquiry on a broad scale, employ competent parties to report upon the subject, and see how far a grand measure might be laid down for the improvement of the whole of the first metropolis in the world.

CONCRETE, ITS INTRODUCTION, COMPOSITION, USES, AND COMPARATIVE EXPENSE.

Concrete was first used in this country by Sir Robert Smirke, at the erection of the Penitentiary at Millbank, afterwards at the undersetting of the walls of the New Custom House, and has been generally used by the above named architect in the public buildings since erected under his care, especially at the club house of the Oxford and Cambridge University in Pall Mall, where the whole area of the building, and to the extent of two feet beyond the line of the lowest footing, was covered to a depth of 2½ feet, the depth being increased to 4 feet under all the walls that rise to the roof; in the specification of the last named building it is thus described. "For the grouted stratum clean river gravel is to be provided, and mixed with lime ground or pounded to a fine powder; it is to be well mixed with the gravel, twice turned over before it is wheeled to the excavation, and it is to be thrown from a height of not less than 6 feet in every part. A man to be kept treading down and puddling the mass as it is thrown down; the proportion of materials to be 6 parts of gravel to one of Dorking, Merstham, or Haling stone lime." It has now become, in the present day, the most favourable expedient resorted to for artificial foundations. Mr. Ranger, of Brighton, improved the above hint by using hot water to facilitate the setting, for which he took out a patent for making artificial stone. A detailed account of the application of Mr. Ranger's artificial stone to the building of docks and river walls at Chatham and Woolwich, is given in the 1st vol. of the *Journal*, being a paper by Lieut. Denison, from the Papers of the Corps of Royal Engineers. Analogous to concrete is beton, from which it differs, in broken stone being used instead of gravel, in the proportion of two of stone to one of lime or pozzolana of Italy, a description of which, taken from the *Franklin Journal*, appeared in Vol. 3, page 265, of your valuable periodical. Since the introduction of concrete, some little difference of opinion as to the proportions of materials and manner of mixing them has arisen among engineers. I therefore give the composition from several specifications:—No. 1. The concrete to consist of 5 parts of clean gravel, perfectly freed from loam or clay, with a proper proportion of small gravel and sand, as well as large, and one part of lime measured dry, the lime to be mixed into a perfectly smooth uniform paste, as for the mortar, but with more water, and then thoroughly mixed with the gravel.—No. 2. The concrete to be composed of sandy gravel and well burnt lime, in the proportion of 3 of the former to 1 of the latter. The gravel to be free from all earthy matter, and the pebbles not to exceed one inch in diameter.

The lime is to be used in a hot state when slacked, and to be immediately mixed, using no more water than is sufficient to incorporate them. After being twice turned, it is to be wheeled on to a stage 10 feet high, and let fall into the trench; it is not to be puddled or disturbed in any way until perfectly set.—No. 3. All concrete must be composed of gravel perfectly clean, and mixed with fresh well-burnt lime in the proportion of 6 of gravel to 1 of lime. The lime and gravel to be mixed in a dry state, and a sufficient quantity of water afterwards added.—No. 4. Concrete to be composed of good lime, gravel, and sand, in the proportion of $\frac{1}{7}$ to $\frac{1}{9}$ of lime, and it should be laid in about 12 inch layers or courses, and pitched from a height of 10 to 12 feet, neither should it be disturbed until properly concreted and set.

In the above five opinions, including that of Sir Robert Smirke, we have the relative proportions of gravel and lime, varying from 3 to 9; and No. 1 states the lime and water to be first mixed, in which No. 2 nearly coincides, whilst No. 3 insists on the gravel and lime being first mixed, and then the water added; Nos. 4 and 2 coincide that the concrete is not to be disturbed after it is thrown into the trench, whilst Sir Robert Smirke expressly states that parties are to be employed puddling the mass. The whole are agreed in specifying that the material is to be thrown from a height. From considerable practice and experience in the mixing of concrete, I think that the lime need not be ground, but simply mixed with the gravel, and then, by the addition of water, it will fall to an impalpable powder, also that it is unnecessary to be at the expense of puddling the mass after being deposited in the trenches, neither is there any advantage to be derived from discharging the mixture from a height, both of which operations increase the expense of the concrete, and as the concrete in the act of setting expands in bulk, I think that alone a sufficient proof of the inutility of both of the above mentioned operations, their tendency being to condense the mass, whilst its own natural tendency is to expand. With respect to the proportion of lime and gravel, I think the less lime the better will be the concrete, and that the proportion of 8 to 1 of lime is decidedly better than 3 of gravel to 1 of lime. As to the quality of materials employed, the lime must be stone lime, fresh from the kiln; that from chalk will not do, and hydraulic or lias lime is to be preferred to stone limes. With respect to gravel, if obtained from a pit, the ochereous or ferruginous is to be preferred, and if loam is present, so as to soil the hand, the gravel must be washed, if the gravel be obtained from rivers by dredging, alluvial and vegetable deposits are to be avoided; and if the gravel contain vegetable refuse, it must be screened or washed. Shelly sharp gravel is the best, the proportion of small or large pebbles, and the due quantity of sand, is soon learned with a little practice.

As to the uses of concrete, it is principally adopted as an artificial foundation, and from four to six feet is a sufficient depth, and extending two feet beyond the space to be occupied with the building. The following testimony of the utility of concrete, is from Weale's Bridges, page 31. "Piling will probably never be found more safe than a body of concrete; the latter cannot be too much esteemed, for its durable and almost imperishable nature, besides being quite as safe and, perhaps, more durable than piling;" and from the paper of Lieutenant Denison, before alluded to, we have the following ratification of its uses. "Concrete cannot be advantageously employed as a building material." "It may be employed with advantage in backing retaining walls." I. K. Brunel, Esq., C. E., has used concrete as a foundation, nearly exclusively and universally in the bridges on the Great Western Railway; and in the celebrated bridge of Maidenhead, the land arches are backed with concrete, to the depth of 10½ feet, and the abutments of the large arches are also backed with concrete. In culverts underneath embankments, the same able engineer has extensively used concrete as a backing material, the brickwork being kept thin, and then enveloped in a mass of concrete, in the form of a polygon, of six sides, or, of the form of two truncated cones, with their bases joined.

Concrete was used on the Great Western Railway, wherever it could be employed, as a backing material; its use is now rapidly extending to the provinces, and bids fair to supersede all other means now employed for making a foundation; it is much improved by being mixed with oxide of iron, smith's scales, and roasted iron stone, or any material containing iron. As regards the comparative expense, brickwork being the most common building material, has been taken as the standard of comparison with concrete for price, and its cost in most districts will be found from one-third to one-sixth the price of brickwork, taking a cubic yard as the quantity of each material, the latter will cost 5*s*. and the former 21*s*, both, to a great extent, being regulated by the vicinity of brickyards, and the facility of obtaining gravel. I have known concrete executed at 3*s*. 3*d*., 3*s*. 6*d*., 4*s*., 1*s*. 6*d*., 5*s*., 7*s*. 6*d*., 8*s*. 6*d*., and 11*s*. 6*d*. per cubic yard, although the most common price is 7*s*. 6*d*.; as to brickwork, the general price is 21*s*., and the range is from 14*s*. to 27*s*. 6*d*. per cubic yard. The London price being 25*s*. per cent. dearer than the country. The facility of obtaining lime regulates the cost of concrete; the price of lime per cubic yard, measured dry in clots, at Dorking in Surrey, is 11*s*.; Barrow in Leicestershire 21*s*.; Bulwell in Nottinghamshire 9*s*. 6*d*.; Breadon in Derbyshire 15*s*. 6*d*; Harefield in Buckinghamshire 16*s*. 6*d*.; Fulwell, Durham County 9*s*. The measures of lime, also, vary much; in some places it is sold by the cubic yard, measured dry, which is decidedly the best method adopted; it would be desirable if it was universal. It used to be sold in London by the hundred, as it was called, not of weight, but a measure, a yard square, and a yard and one inch deep, which will be equal to 16 or 18 bushels, but it is now sold by the cubic yard. The Folwell and Barrow lime is sold by the quarter, eight of which make a ton and a half. Lime is also sold by the boll and chaldron; a chaldron will be about 3½ tons, a single horse cart about six bolls. In agricultural districts, the bushel, boll and quarter are used; in colliery districts, the chaldron and ton are the standard of measure. With respect to the cost of gravel, provided it can be obtained on ground belonging to the company, the getting, screening, and cartage will cost 1*s*. 6*d*. to 2*s*. per cubic yard; if it be obtained from the gravel pits of the country, the charge will be per ton, from 2*s*. 6*d*. to 2*s*. 9*d*., if screened 3*s*. 3*d*. to 3*s*. 10*d*., if broken 6*s*. 10*d*. A cubic yard will weigh from 24 to 27 cwt. If the gravel is dredged or brought from the shores of a river, the cost will be 2*s*. 6*d*. per yard, or nearly the same as from the pit. The prices of the various operations of getting, screening, and washing gravel are respectively 10*d*. and 12*d*. per cubic yard. The price of excavation is also included in the price of concrete in all railway specifications, which will be about 4*d*. per cubic yard, as generally the excavation is of limited extent, and consequently more expensive than an extensive excavation, and when the gravel is obtained on the ground of the Company or proprietor, the excavation is a double operation, the hole having to be refilled with other materials in lieu of the gravel obtained. From the experience of several thousands of yards and variety of situations, I find the cost of mixing the materials, or as it is termed concreting, to be 1*s*. per cubic yard, and taking the proportion of material at 5 to 1, the following will be a fair estimate of the cost of concrete:—

		s.	*d*.
1 cubic yard of lime	- - -	12	6
5 do of Gravel at 2*s*. 6*d*.	-	12	6
Labour mixing at 1*s*. per yard	-	6	0
6 yards of excavation at 4*d*.	-	2	0
Waste, contingencies and profit, at 1*s*.		6	0
6 cubic yards, at 6*s*. 6*d*.	- =	39	0

Concrete will set in 24 hours; the specific gravity is 125, or about the same as brickwork, although brickwork is sometimes 165 lb. per cubic foot. Lieutenant Denison gives the strength of concrete $S = \frac{lW}{4bd^2}$ The constant S being 9·5, and comparing concrete to York paving, the proportion is as 1 to 13.

The following works may be consulted; Colonel Pasley, on Calcareous Cement: Weale, 1839;— Aikin on ditto, in Transactions of Society of Society of Arts:—Lieutenant Denison's Notes on Concrete, from papers of Corps of Royal Engineers, *Journal*, Vol. 1, p. 380; Lieutenant-Colonel Reid, ditto, see also the *Journal*, Vol. 1, page 134: a letter on concrete, by a Constant Reader, Vol. 3, page 265, Vol. 5, pages 58, 276.

I am, &c.,

WIRE ROPE LIGHTNING CONDUCTORS.

Sir—Having seen, in some of the recent numbers of the *Mechanics' Magazine*, a long discussion as to the priority of claim, respecting the wire rope as a substitute for metal rods, in conductors, I beg to call your attention to a paragraph, which appeared in a work, published by Sir John Herschel, more than 10 years ago. He says thus; that wire rope has long been used at Munich in preference to metallic rods, for lightning conductors. I think this proves that the subject has been long tried and practised, before Mr. M. J. Roberts brought forward the subject.

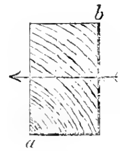
WROUGHT IRON AXLES.

Sir—It is worthy of remark how slowly well proved facts, individually acknowledged and acted upon, become generally admitted; it is to be regretted that we are not more communicative of those events which strike us in our daily practice, and which, if announced as soon as discovered, would so materially and rapidly tend to general improvement. There is, perhaps, no instance in which this can be more clearly exemplified than in the use of wrought iron; it is scarcely possible to refer to the subject without an example being readily laid before you. Every manufacturer has had more or less his attention drawn to the fact, that in its various applications wrought iron is subject to become brittle. Iron spindles, piston rods, fire bars, crow bars, chisels, and many other things, are known to lose their fibrous quality after being in use for a length of time, varying according to the nature of the service they have had to perform. By some it has been considered that the iron originally employed was of bad quality, and the circumstance when discovered has not been otherwise attended to than by replacing the broken piece; but in many instances the phenomena has been clearly established, closely examined, and well attended to, and that for years together, without, however, having become a generally acknowledged fact, sufficiently positive to justify the opinion that wrought iron, applied for certain purposes ought only to be allowed to perform a previously determined quantity of work, after which it becomes requisite to re-forge the piece.

In most cases the fracture may be unattended with danger to human life, but in others, as in connexion with railways, where hundreds of lives may depend on the strength of an axle, it daily becomes more evident that extraordinary precautions must be resorted to for the purpose of avoiding accidents, and I would, with regard to railway axles, suggest (as a precautionary measure) the propriety of limiting the distance they should be allowed to run previous to their being thrown out as unfit for service, and that whether apparently in good condition or not. Such is the perfection with which these axles can now be manufactured, that when a suitable quantity of iron is used, it may be confidently asserted that every axle turned out of the shop after due examination may be considered to be sound, and that by limiting the work it is allowed to perform, the fracture of an axle would become a very improbable event.

Having been lately in Paris, I mentioned the circumstance to M. Arnoux, the directing manager of the extensive works belonging to the Messageries Laffite & Caillard, persuaded that from a person whose attention has been for so many years engaged on this subject, I should obtain some positive information; he showed me a number of axles which he had caused to be broken, after they had performed their allotted quantity of work; they all broke short and brittle, the fracture invariably indicating the progress of the disease. The fracture commences at the lower angle of the axle on the side of the traction, which is evidently in fixed axles the point of greatest fatigue, and in those axles which have given way under the weight of the load, the fissure has in some instances nearly traversed the axle before it broke entirely, and it is then very easy to trace the accident from its engine. I will endeavour to describe its usual appearance by the following diagram; the arrow shows the direction in which the carriage moves.



The fracture invariably originates at the angle *a*, and appears to progress at intervals by zones as shown by the lines in the diagrams, the first, at the point *a* becoming perfectly black, the colour of each being lighter as they gradually extend from this point, and as the contact of the two sides of the fracture becomes more intimate, the grain of the iron towards the angle *a* is coarse, and has a large crystalline texture, which diminishes in size as the fracture approaches the angle *b*, at which point the metal remains slightly fibrous, having evidently undergone a more rapid deterioration at its point of greatest strain.

M. Arnoux informed me, that in consequence of this effect, to which he has for a long time paid great attention, he has come to the conclusion that an axle can only safely run a distance of 30,000 leagues, or about 75,000 English miles; when an axle has run that distance, he invariably takes it out, places it between two new bars of iron, and welds them together so as to form a new axle. If the carriage usually runs over a paved road, such as is frequently met with in France, the axle is not allowed to run so great a distance, and a certain degree of wear in the collar then determines the period at which the axle is thrown out, not in consequence of the wear of the collar, but because that degree of wear has proved, by experience, that it is prudent to renew the axles in order to avoid a fracture.

Here, then, we have the proof of an important principle in the application of wrought iron, being well established and long known to one, and probably to many individually, without having come to the knowledge of railway engineers, who are thus compelled to arrive at this important truth by dint of actual experience, obtained through the medium of a series of lamentable accidents, and they could not acquire their information in any other way, unless made acquainted with the circumstance by those who have previously purchased their knowledge.

The question, then, admitting the above statement to be correct, will be, how great a distance it may be prudent to allow railway axles of different descriptions to run; and to solve this question, it will be advisable, in the first instance, to adopt a term which may certainly be within the limit of perfect safety, until the greatest distance that can be safely adopted may have been determined by a series of well conducted experiments.

Iron exposed to great heat undergoes the same kind of deterioration. I examined, in the same establishment, several bars taken from a furnace in which they heat their wheel hoops; the part of the bar directly exposed to the fire offered the same crystalline appearance as the broken axles, which gradually diminished towards the end that was out of the fire, and the end of the bar which was out of the fire altogether, had the appearance of good tough iron. The portion which had suffered most from its direct contact with the heat, having been doubled over and welded entirely, recovered its fibrous quality, and stood a cold bend as well as any iron that had not been in the fire.

Should you find this communication worthy a place in the *Journal*, you will oblige, by its insertion,

Your obedient servant,

20th January, 1843. H. H. Edwards.

SELF-REGULATING EXPANSION SLIDE VALVE.

Fig. 1.

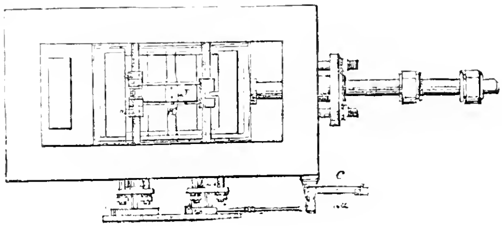


Fig. 2.

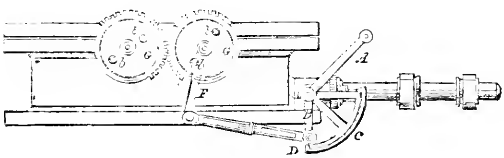

Fig. 3.

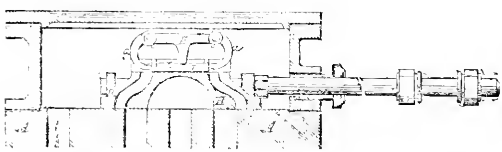

Improvement in the steam engine is so much sought after, so many are engaged in the pursuit, and economy in the consumption of fuel is a question of so much importance, that no apology need be offered on presenting a plan to attain that object, and which has been found here or elsewhere to be an absolute improvement.

The simple apparatus which I am about to describe, (for which I obtained two patents abroad,) has been applied very successfully, and is now getting into extensive use. I believe it to be unknown in this country, except to a few persons to whom I have explained it; and as it will on most occasions be found to be useful, I propose to make it known through the medium of your truly valuable columns, which being open to communications of the kind, and much read, I should be happy to introduce this to your readers through so respectable a channel.

The advantage of using steam expansively does not require demonstration, it is too universally acknowledged to admit of any doubt; I must, however, enter a little into the subject, to point out the benefit to be derived from the application of my slide valve, but will endeavour to be as concise as possible.

An engine working without expansion, receives the steam on its piston during the whole length of stroke, its speed being regulated by contracting more or less the passage through the throttle valve, thereby to a certain extent wire-drawing the steam. The speed of the engine is effectually regulated by this means, but a considerable quantity of steam is thereby thrown away, as I will endeavour to show.

It frequently happens that an engine is lightly loaded, and as the loss to which I allude is comparatively greater with a light load than with a full one, on account of the wire-drawing becoming more complete, I will take for example an engine working with such a load as will require the orifice through the throttle valve to be sensibly contracted, in order to keep down the speed of the piston.

When the engine passes over her centre, the motion of the piston is very slow, and the orifice of the throttle valve will allow the steam to rush into the cylinder in sufficient quantity to exert its full pressure; but as the speed of the piston increases, the quantity of steam admitted becomes insufficient to fill the space at full pressure behind the piston.

The piston continues increasing in speed until it reaches the middle of the cylinder, where it is the greatest, from that point to the end of the stroke the speed decreases until the motion is reversed; there is necessarily a point of the stroke at which the speed is so slow, that the quantity of steam admitted through the throttle valve will be proportionate to the speed of the piston, and from that point until the end of the stroke, as the speed of the piston decreases, the steam will accumulate in the cylinder, and the pressure will increase; but at that moment the position of the leverage of the crank is such, that the increasing pressure of the steam produces comparatively little effect on the speed of the engine, and at the moment at which the pressure reaches its maximum, the slide valve is reversed, and the contents of the cylinder are thrown into the condenser.

The quantity of steam thrown into the cylinder at the beginning of the stroke is not lost, because it continues to act expansively on the piston, and becomes a portion of that volume of steam which determines the speed of the engine and the relative steam passage through the throttle valve; but as I said above, the volume of steam thrown in towards the end of the stroke, only serves to fill the cylinder uselessly at the moment when its contents are about to be thrown into the condenser.

If the engine happens to have a light fly-wheel, the evil is considerably increased, because the speed of the engine will sensibly decrease towards the end of the stroke, the orifice of the throttle valve will be enlarged by the action of the governor, and an increased volume of steam will be admitted into the cylinder just in time to be thrown away.

By working the steam expansively, the above-mentioned loss is avoided; and if the resistance to be overcome was constant—as for instance, to raise a given quantity of water to a given height in a given time—then the fixed expansion would answer every purpose; and this is, perhaps, the only instance in which that can be said to be the case.

Generally speaking, the load is variable, and when that is the case, the point of the stroke at which the steam is cut off should also be variable, so that the steam employed should exert its full pressure while it is being admitted to the piston, in order to produce the full effect of expansion from the moment it is cut off until the end of the stroke.

For this to be carried out efficiently, the engine itself must determine the point of the stroke at which the steam should be cut off, and the governor is sufficient for the purpose. I think I may infer, that the valve hereafter described, will be found useful *for all engines which require a governor to regulate their motion.*

The present system of advancing the eccentric, and constructing the working valve, so that the steam is cut off at about three fourths of the stroke, is an immense improvement, but stops short of what is wanted, particularly for those engines which work with high steam.

The elasticity of steam being subject to the same law that governs the elasticity of atmospheric air, as determined by Mariotte, the elasticity being proportionate to its density, then a volume equal to 200 under a pressure = 2, will be reduced to 100 under a pressure = 4, and will expand so as to represent 400, the pressure being reduced to = 1.

This being the case, let us suppose the length of the stroke of the cylinder of a steam engine divided into 20 equal parts, and that steam of four atmospheres is acting upon the piston during the whole of the stroke; the consumption of steam will be represented by $20 \times 4 = 80$, and the sum of the forces will also be $20 \times 4 = 80$; in this case the consumption of steam will be as 1, and the power exerted will also be 1.

Take the same cylinder, and admit steam of the same pressure during $\frac{15}{20} = \frac{3}{4}$ of the length of stroke, the quantity of steam expended will be $15 \times 4 = 60$, and the sum of the forces will be $15 \times 4 = 60$ for the first 15 spaces, and 16·77 for the remaining 5.

The consumption of steam will be 60 = 1.

The power exerted will be 60 + 16·77 = 76·77 = 1·27.

(See diagram No. 1.)

Again, in the same cylinder, admit the steam only during $\frac{10}{20} = \frac{1}{2}$ the length of stroke, the quantity of steam used will be $10 \times 4 = 40$, and the sum of the forces will be $10 \times 4 = 40$ for the first 10 spaces, and for the remaining 10 spaces it will be 26·75.

The consumption of steam in this case will be 40 = 1.

The power exerted will be 40 + 26·75 = 66·75 = 1·66.

(See diagram No. 2.)

No. 1.		No. 2.		No. 3.
0	0	0	0	0
4	1	4	1	4
4	2	4	2	4
4	3	4	3	4
4	4	4	4	4
4	5	4	5	4
4	6	4	6	3·333
4	7	4	7	2·857
4	8	4	8	2·5
4	9	4	9	2·222
4	10	4	10	2·
4	11	3·636	11	1·818
4	12	3·333	12	1·666
4	13	3·076	13	1·538
4	14	2·857	14	1·428
3·75	15	2·666	15	1·333
3·52	16	2·5	16	1·25
3·34	17	2·352	17	1·176
3·17	18	2·222	18	1·111
3·	19	2·105	19	1·052
6·78	20	2·	20	1·
46·28		66·74		46·28

Carry this again further out, by admitting the steam only during $\frac{5}{20} = \frac{1}{4}$ of the stroke, and we shall find for the expenditure of steam $5 \times 4 = 20$, and the sum of the forces for the first five spaces will be $5 \times 4 = 20$, and for the remaining 15 it will be 26·28.

The consumption of steam in this case will be 20 = 1.

The power exerted will be 20 + 26·28 = 46·28 = 2·31.

(See diagram No. 3.)

To obtain the greatest possible advantage from steam it is requisite:

1st. To employ it expansively.

2nd. To admit it into the cylinder at its full pressure without being wire-drawn.

3rd. That the portion of the stroke during which it is admitted freely, should be determined by the engine governor.

The construction of this self-acting slide expansion valve, will be understood by inspection of Figs. 1, 2:

A, being the face of the cylinder.

H, the slide valve, acting exactly the same as the ordinary slide valve.

I, a moveable metallic plate, worked by friction against the back of the slide valve H, as far each way as will be permitted by the cam or tappet *a*, the position of which will be determined by the governor.

When the points of the tappets are approached so as to hold the plate I, the slide valve H, alone will move, and the steam will act only during a very small portion of the stroke of the piston.

When the points of the tappets separate, the plate I, will be carried along with the valve, until brought in contact with the tappets, and the greater the distance between the points of the tappets, the longer the steam will be admitted into the cylinder.

When the tappets are sufficiently thrown back to prevent the plate I, from reaching them during the whole length of the stroke of the valve, the fixed bracket K, will then place the plate I in the middle of the slide valve, and the steam will be admitted during the whole length of stroke of the piston, with the exception of what portion may be cut off by the advance of the eccentric.

The two spindles which carry the tappets *a*, pass through stuffing boxes reserved on one side of the valve box, and are turned by two sectors fixed on their extreme ends, and working into each other; the tappets therefore move simultaneously in contrary directions, a lever fixed to the top sector being worked by the governor, so as to separate the points of the tappets *a*, as the speed of the engine diminishes, and to approach them nearer together as the speed increases, and in this way steam will be admitted in such volumes into the cylinder, as will effectually regulate the speed of the engine without ever contracting the orifice of the throttle valve.

This summary explanation is quite sufficient to show the principle upon which this valve is constructed, and by what means the purpose is effected; what follows, is a somewhat more detailed account of the same, useful only as entering a little more minutely upon the subject, and giving some instructions to be attended to in its construction.

To facilitate the setting of the metallic plate I, attention must be paid to the position of the tappets *a*, because upon their position depends the proper effect of the valve. The upper sector G, is keyed on the end of the spindle, and the lever F, is fixed to the sector by two screws *b*, running through oval holes in the sector, which permit the spindle to be turned a little either way, so as to move the points of the upper tappets a little nearer to, or a little further from the plate I.

On the lower spindle the same facility is obtained, by keying a plate on the spindle, instead of fixing the sector itself, and then by fixing the sector to the plate by two screws, giving play in the holes as above, the bottom tappets can also be varied as may be required.

To cause the plate I to adhere to and follow the vale H, in its motion, a spring K, is fixed on the back of the plate I, and the two ends of the spring slide in a groove, formed by two side pieces fixed to the slide valve; this spring is so disposed as to press the plate against the back of the valve.

I have occasionally applied this valve to engines that required to have more steam thrown on to one side of the piston than on the other, and have thereby been able to do away with a considerable counterweight—for instance, in direct engines, where there is considerably more weight in the down than in the up stroke, I have found it very useful; and in another case, in which a cold water pump was attached to one end of the beam, and lifted water from a very deep well.

The motion of the valve being determined by an eccentric, is exactly the same as that of the piston determined by the crank, but with this condition, that the valve is at its greatest speed while the piston is at its lowest.

If the circle described by the crank pin is divided into equal parts round its circumference, the motion of the piston, commencing from the end of the cylinder, will increase as the versed sine of the arc described, until it reaches the middle of the cylinder, while that of the valve will be as the sine of the arc; and as the difference of the versed sines is constantly increasing, while the difference of the sines decreases, the result will be, that the motion of the plate I, on the back of the valve, must be less the longer the steam has to act upon the piston. The spindles of the tappets must therefore be worked by a motion of the same description as that of the eccentric, and this is obtained by means of the bell crank, A, B, the long arm A being worked by the governor, and made to describe an angle of 90°, the arm B, being horizontal when the governor balls are open, and vertical when they are closed; a graduated quadrant C, being fixed against the valve box, a hand fixed to the extremity of the arm B, of the lever A, B, will show during what portion of the stroke of the piston the steam is admitted into the cylinder.

The pin being pulled out from the lower joint of the lever E, the lever F, will be thrown up by the action of the plate I, against the tappets; the plate being no longer stopped by the tappets will be directed into the middle of the slide valve by the fixed bracket K, and the steam will be admitted to the piston until cut off in the usual manner by the slide valve.

When it is requisite to stop the engine, this pin must be withdrawn, because it is requisite that the plate I, should be always in the middle of the back of the slide valve to be ready for starting; the small quantity of steam that would otherwise be admitted would not suffice to start the engine.

This valve, which I have applied to a great many engines, and which has also been applied by others, answers perfectly well; it is, therefore, not merely a speculative idea that I am laying before your readers.

I applied one pair of them to a locomotive engine, but the result was not so favourable as I anticipated; not that this valve is not applicable to this kind of engine, but because I applied it in an improper manner, and without having beforehand taken into due consideration the several points in which the locomotive differs from other engines. I considerably increased the power of the engine, but did not save fuel, which is one of the principal objects I had in view. I made the cylinder too large; and did not sufficiently provide for the very great speed with which the piston of a locomotive travels, so that I produced in the slide valve the wire-drawing of the steam, which I avoided in the regulating valve; it must also be observed, that a sufficient blast must be determined in the funnel, to secure the generation of a sufficient quantity of steam; this was provided for, but in an improper manner, being only obtained by contracting the orifice of the blast, which would only enable me to obtain a proper effect under a given load and upon a constant gradient; and as on a railroad these two conditions are constantly varying, it is evident that the area of the orifice of the blast should vary also, not only when the steam is worked expansively, but on all occasions. I therefore took out a patent for an apparatus, by the use of which, the blast could be regulated with the greatest nicety, and obtained permission to make a series of experiments with the apparatus, on one of the most powerful locomotives, unfortunately not the one to which the expansion valve was applied, and the result was, what might have been anticipated; the variable blast did not require any assistance, and acted perfectly well in every respect; whereas the expansion valve, which requires absolutely the variable blast, did not produce its full effect without it.

From the very liberal conduct of the company, I am persuaded, that if I had remained longer in France, they would have authorized me to complete these experiments; but family affairs having called me back to England, they remain in an imperfect state, as far as regards locomotives. I, however, went far enough with the experiments to feel convinced, that by the application of the expansion valve in conjunction with the variable blast, a considerable improvement would be effected in the locomotive engine.

London, 19th October, 1842. H. H. Edwards.

Improvement in the Manufacture of Gas.—A workman employed at Esk Mill, Edinburgh, named J. Lothian, is said to have perfected a most important improvement, whereby a saving of one-half of metal, fuel, and fire, is effected by a new construction of the flues, and situating of the retort. His principle of building flues is also said to be well worthy the attention of those having small establishments, where gas is required. A few days since, he made, in 4½ hours, by one small retort, 846 cubic feet of gas, the same being prepared from various substances.

THE YORKSHIRE ARCHITECTURAL SOCIETY.

Sir—However well-intentioned the regulation may be, that all who are admitted into this society "must be members of the Established High Anglo-Catholic Church," it appears to me to be one of a very questionable kind, whether as regards propriety or expediency. What is exactly meant by the Anglo-Catholic Church, I for one, know not, the term being to me altogether a novel one; but let it mean what it may, it seems that Anglo-Catholicism does not interfere with the "*peculiar sentiments*" of those who profess it! This, however, is touching upon different ground; what I have to object to, is the mixing up religion at all with secular matters, for the doing so is apt to lead to the former being made use of as a mere stalking-horse, and rendered subservient to worldly interests.

Had the restricting *sine quâ non* been that all members must be thoroughly acquainted with *Ecclesiastical architecture*, that would have been a very intelligible and proper regulation, and would have answered every purpose, if it really is supposed that no one who is not likewise a member of the Anglo-Catholic Church, can have suitable feeling for, or do justice to that particular style of the art. Or if such be not the case, why should the society exclude architectural talent and ability merely because they may not happen to wear the badge of what it holds to be religious orthodoxy?

If such affected strictness be not *cant*, I know not what is. As far as religion is concerned, it would perhaps be more honest and more consistent on the part of the Protestant church, sternly to reject at once and altogether, whatever, in any degree, partakes of, or reminds us of Roman-Catholicism, its idolatrous worship, its vain and puerile superstitions. Instead of deploring the barbarous spoliations and ravages committed by iconoclasts and puritans, we ought to abstain from attempting in any degree to revive or encourage a taste for a style of architecture, to which we can never do complete justice, but at the very best must always remain immeasurably behind the original models, if merely because we neither have occasion for, nor can possibly admit into our churches, that amplitude of space, and that prodigal display of architecture and art, which, if it does not imperiously demand it, Romanism regards as manifestation of piety. For our churches, we require no long array of ailes and chapels; neither splendid sacristies, nor gorgeous altars: we have neither processions, nor saint-worship; in fact, do not even know anything of, or in any way recognise, many of the saints to whom our churches are nominally dedicated, or rather merely called after for form's sake, and in order to distinguish one building of the kind from another in ordinary discourse. What are St. Giles, St. Pancras, St. Olave, St. Chad, &c., to us Protestants, except so many names, which might as well be those of Egyptian kings?

Therefore, if such matters are of no moment—no scandal to our Protestantism, why should we now become all at once so excessively scrupulous in regard to what are equally matters of indifference? If it can be shown that it is indispensably necessary a man should belong to the Anglo-Catholic Church, in order to acquit himself worthily in building churches, let it be done.

Rickman, who understood Gothic architecture and our ecclesiastical buildings, as well or better than most in the profession—although Gwilt has not thought either him or his work worth any mention—was brought up in the tenets of quakerism, which, though it did not prevent his being employed professionally at some of the colleges at Cambridge, would now have excluded him from the Yorkshire Architectural Society.

It may be said that all this has scarcely anything in common with the objects of your *Journal*, and it certainly ought not; but if people will mix up religion and party spirit, such matters must unavoidably be agitated, and find their way into publications like your own. If qualification of any kind be required from those who seek to become members of the Yorkshire Architectural Society, it would surely be sufficient precaution against the admission of the unworthy, were it made a law that every one—at least every one actually belonging to the profession—should send in as a testimonial of his ability, some original study or design in ecclesiastical architecture; and if his taste should be found orthodox, he might be allowed to pass muster without inquiry as to the orthodoxy of his religious tenets.

I remain, &c.,

Q. E. D.

CANADIAN BOARD OF WORKS.

Sir—As you have uniformly taken high and strong ground when discussing the policy of constructing public works by Government, viewing the system as injurious to the community as it is degrading, and indeed, ruinous to the profession, the following remarks on some of the works now in progress or to be soon undertaken by the provincial government of Canada, may not be without interest to your readers. I believe this the more readily, as you some time since (Vol. III, p. 122 et seq.) copied an article from the American *Railroad Journal*, showing the, in every way, injudicious and demoralizing effects of the system here, which paper I should have had much pleasure in condensing for, and otherwise adopting to the English reader, had I supposed the communication useful to you otherwise than as a reference. What I now offer on the public works of Canada, will only too clearly show, that it is not easy to speak too strongly of the wretched system of carrying on these undertakings by agents of government, and with the public money, without any other responsibility than that to party.

My remarks will be confined almost exclusively to the "Improvement of the St. Lawrence," by canals round the rapids above Montreal. These canals are three in number.

1. The Lachine canal, round the Lachine rapids, connecting Montreal with Lake St. Louis, a distance of nine miles. This canal has been in operation nine or ten years, and the locks are 100 feet long in the chamber, 30 feet wide, and 5 feet deep.

2. The Beauharnois canal, on the other or south-east side of the St. Lawrence, connecting Lake St. Louis with Lake St. Francis, round the Cascades, Cedars, and Coteau rapids. This canal was commenced in July last, will be from 12 to 15 miles long, is to have locks 200 feet long in the chamber, 45 feet wide, and 9 feet deep on the sill—total lockage 82 feet, prism of canal 120 feet at water line, 80 feet at bottom, and 10 feet deep. Estimated cost £255,900 currency = £214,000 sterling.

3. The Cornwall canal connecting Lake St. Francis with the river above the Longue Soult rapids. This canal is nearly or quite finished, is 11½ miles long, with locks 200 feet long, 55 feet wide, and 9 feet water on the sill. Prism of canal 110 feet at water line, 100 feet wide at bottom, and 10 feet deep. Lockage about 48 feet, cost above £400,000 currency, without any protection to the inner slopes: a precaution found indispensable on the enlarged portions of the Erie canal, (which are only 70 feet at water line, 42 feet at bottom, and 7 feet deep. Locks 110 feet long, and 18 feet wide.) The excavation of the Cornwall canal was very heavy.

Besides these, there will be several short canals round some of the worst points in the river, which, for the next 35 miles, has a current of from three to eight miles per hour. The aggregate length will be about 40 miles, and the total lockage about 180 feet.

You will observe that the Beauharnois canal has been commenced on the *south* side of the St. Lawrence, in justification of which the chairman of the board of works wrote the letter, a copy of which, in a Montreal paper, I forward to you. The gentleman, in consequence of whose remonstrance this was written, engaged me to examine the question, and, finding no data, or indeed, any engineering information whatever in that paper, I was under the necessity of making such surveys as would enable me to give an opinion, which was to the following effect, that, the incidental works being trifling, and the lockage of course the same on both sides, the difference in cost, £105,000, must be sought for in the earth-work. But, the total cost of this on the north side, was, by my estimate, only £110,000, or, by the prices of the board of works, about £95,000, so that the difference of £100,000 became quite impracticable, as is indeed at once obvious to any eye at all accustomed to judge of ground. *After* my reports were laid before the select committee at Kingston, the board sent in their "estimates," unaccompanied by any report, in which they make out their case; by,

1. Comparing the *worst known* line on the north side; that is, the *last* line run by the board, and designated as No. 10 in the letter I send you, with the best line on the south side, thus making a difference of £40,000 against the north side.

2. By comparing a canal 15 miles long on the north side, reaching from still water to still water, with a canal 12 miles long on the south side, having its western terminus at the foot of a strong current, with extensive rocky shoals between the mouth of the canal and Lake St. Francis, difficulties, which I showed in my evidence, it would cost at least £40,000 to overcome.

My reports will be found in the evidence, a copy of which will be sent to you, and they will enable you at once to sift the facts from the vast quantity of irrelevant matter, with which the board have endeavoured to mystify the very simple points on which the investigation turns.

I will now request your attention to a dispatch of the Colonial Secretary to the Governor-General, dated 2nd of April, 1842, in which Lord Stanley writes: "It can hardly be doubted that works so extensive, and calculated to produce such important results, ought to be superintended by the best professional assistance which it is possible to obtain. Her Majesty's government entertain no doubt of the anxious desire of the Canadian Board of Works to discharge with fidelity the arduous duties which will devolve upon them; but I can as little doubt the anxiety which they must feel to have associated with them in such a trust, the best professional assistance which it is in the power of the mother country to furnish.

"It is therefore, my intention, in anticipation of the acquiescence, which I cannot for a moment doubt, of the colonial legislature, in the general arrangements suggested by Her Majesty's government, to send over an officer of engineers, whom, as Her Majesty's commissioner, I trust the legislature will have no difficulty in associating with the board of works, in the superintendence of the works to be undertaken; and whose experience may probably enable the undertakings to be conducted with the efficiency and economy which must be alike the interest of the colony and of this country."

Sir Charles Bagot replies, 28th of April, 1842: "Of course, as her Majesty's government provide the funds with which the public works are to be conducted, it is but reasonable that they should have a share in the management of it, if so desired."

His excellency then goes on to object strongly to a "military engineer," and suggests a "civil engineer," an expense it is well known the home government will not incur; in the mean time the work is commenced before even the centre line or the levels have been established.

Lord Stanley writes on the 2nd of July, 1842: "In your dispatch of the 28th April, you admit the necessity of appointing an engineer officer, as commissioner on the part of Her Majesty's government, to superintend the execution of the works which may be undertaken, and point out the reasons which induce you to prefer a civil to a military engineer.

"On this subject, I have only to observe, that if provision be made by the legislature for the payment of such an officer, (which, I agree with you, will be very desirable,) Her Majesty's government would have no preference for a military over a civil engineer, nor any wish on the subject, but to procure the services of the most competent person who could be engaged for this purpose."

Now, I have no hesitation in asserting, that, had this officer been sent out the canal could not possibly have been placed on the south side of the St. Lawrence. For, the examinations which he would have found it his duty to make, *before* giving his acquiescence, would have shown him that the south side had no advantages in an engineering point of view; and no English engineer, civil or military, could well tolerate the position of the Governor-General, that "ceteris paribus" he should "*probably*" (!) give the preference to the north side. The stern reply of Lord Stanley to this flippant remark, in which he expresses "his regret" at the "sacrifice of the military advantages" of the line on the north side of the St. Lawrence, cannot fail to strike you as proper and manly, as well as decidedly called for.

But the great object of the work is commercial; and, in this point of view, the examinations of the engineer of Her Majesty's government, would have shown him, that the line on the south-east or *lee* side of the St. Lawrence, must on that very account, and with any expenditure, be *somewhat* inferior to the line on the north-west side; in other words, that the "military advantages," so highly prized by Lord Stanley, were to be "sacrificed" not to aid, but rather to injure the commercial interests of the country. So general is the belief in the want of common honesty evinced in this transaction, that the large sum (£30,000 or £40,000) already expended on the south side, constitutes *now* the only argument in favour of continuing it on that side of the river. I am, however, of opinion, that this will avail little, if Lord Stanley send out an engineer—civil or military, I care not which—who, with even a little practice, is not deficient in self-respect and integrity. Such a man will soon discover, that a canal adapted to the trade of the country, will be worth more, both as regards facility of working, and—what is most important—low tolls; which latter must obviously be in proportion to the cost, than a canal of the present preposterously colossal dimensions. Hence, even £100,000 may be spent on the south side; and the commercial as well as national interests may be advanced by the construction of a canal on the north side, in such a manner and of such dimensions as prudence, experience, and common sense shall point out.

Lord Stanley will hardly brook being told, that, the canal having been commenced, it is useless to look back—that it is better now to submit to the imposition, infamous though it be, than sacrifice the work already done—that the honour of the government will be sufficiently appeased by dismissing the board of works with disgrace, and similar arguments of those whose only escape from a wretched bargain—if so mild a term may be applied—lies in the momentary and imaginary value which the construction of a "ship canal" to the "great lakes" along the Seigneury of Beauharnois may give to that property in the London market. But should Her Majesty's government sift this matter thoroughly, not only may the canal on the south side be stopped, but Sir Robert Peel—the unwavering friend of private enterprise, the grand secret of British supremacy—whose policy would never have originally given the imperial security for £1,500,000 sterling, "*cette pilule dorée*," as it was contemptuously termed by a leading French member of parliament—may feel himself called on to cancel the endorsement, when he discovers that the munificence of the home government serves only to the direct injury of the commercial interests of the colony; to the neglect of the military interests of the present state; of the agricultural interests of the colony; and, worst of all, to the demoralization of the colonial government and people. For, not only does the present course resemble that of the worst of the subsequently repudiating states, but there is superadded a degree of cool and mendacious effrontery almost incredible, on which, indeed, the main chance of success now rests. Thus, after reading Mr. Killaly's letter, you would be surprised to learn, that, the "French engineer" is *supposed* to have been a Canadian surveyor, his very name being even unknown. Survey No. 2, by Mr. Mills, led that gentleman to give the preference to the north side, (Nos. 4, 7, 8, 9, and 10, have obviously no bearing on the question.) No. 5 was by a country surveyor, and he merely points out some disadvantages in one route on the north side. No. 6, Mr. Baird never examined the north side; and, though in Kingston at the time, was not called in by the board; the superior "economy, and facility of navigation," consist in a violent current and lee shore; that a vessel which can navigate the canal, can neither get in nor out at the western terminus; that the three channels are pure fabrications, and that this is not the first extensive public work "undertaken through a district entirely settled and inhabited by Canadians of French origin." The Champlain and Lawrence railway runs through such a country, and was built almost exclusively by these Canadians; the Chambly canal also traverses such a country. On the latter work I served as assistant engineer in 1831; and the former was built under my directions, *by the day*, and opened in July, 1836. The evidence shows all this and much more; but I will proceed with some observations on the commercial prospects of the St. Lawrence canal.

The grand object of the undertaking is to attract to the St. Lawrence a large portion of the western trade, on the assumption, that the larger the canal, the lower the rates of freight; and, secondly, that the cost of transportation from the great lakes to Montreal, is the only drawback to an unlimited trade with the west—positions altogether untenable.

Barges now descend the St. Lawrence from Lake Ontario to Montreal, with from 100 to 150 tons freight, according to the depth of water in the "Cedar Rapids," where the barges frequently touch on the boulders, with which the rocky bed of the river is covered. There is only 4½ feet water here in the autumn, but, by clearing out the channel, it is believed that boats drawing 5 feet water may descend at all times. Such boats would carry 150 tons, or, if made of iron, 200 tons of freight, and with a proportionate reduction in the cost. A bill appropriating £10,000 currency to the improvement of the Cedar Rapids was introduced at the late short session, and the prerogative alone prevented its passing, as it met with universal favour. I send you a sketch of the contemplated plan, with a description in the *Montreal Gazette*, by Mr. Henry Roebuck, the projector of this, the first attempt to improve the downward navigation of the St. Lawrence. The average regular charge is 1*s*. 9*d*. currency per bbl. of flour from Kingston to Montreal, a distance of more than 200 miles by the river = ·195*d*. currency per bbl. per mile = 18*s*. 3¼*d*. currency = 15*s*. 2*d*. sterling per ton of 2240 lb. (Flour was carried during the late summer for 1*s*. sterling per bbl.; and merchandize was carried up for 25*s*. currency = 20*s*. 8*d*. sterling per ton, by the Rideau canal, a distance of 240 miles, during a strong competition.) The *tolls* on the present Lachine canal are 2*d*. currency per bbl. of flour for 9 miles = ·222*d*. currency per bbl. per mile, or more than twice the total cost per mile through, ·105*d*. currency, as above.

The Erie canal of New York, with which these canals are to compete, has locks 90 feet long, 15 feet wide, and 3½ feet water, prism of canal, 24 feet at bottom, 40 feet at water line, and 3 to 4 feet deep. The tolls are 1*s*. 9*d*. currency per barrel of flower for 363 miles = ·0578*d*. currency per barrel per mile = about one fourth the tolls of the Lachine canal! thus showing an immense advantage in favour of the Erie canal—an advantage due to the cheapness of its construction; in other words, to its reasonable dimensions. How then is transportation to be lessened, by expending two or three times its original cost in enlarging the Lachine canal? The high tolls have driven the forwarders to try the Lachine Rapids, and during the past summer and autumn a vast number of boats have gone safely over. There is a great depth of water, but the channel is narrow and crooked. (The descent is about 30 feet in 1½ to 2 miles, which is passed in 4 or 5 minutes, the inclination of the surface of the water being such, that the force of gravity acts on the boat, thus producing a great velocity through the water in addition to that of the current. A heavily laden barge overtook a light steamer in the rapids, fortunately without injury to either—and the first season of this navigation has passed without accident.)

Now were individuals expending *their own* money on these canals, they would endeavour to ascertain whether the income—the true test of the accommodation to be offered to the trade—would justify the construction of canals of a size unknown, in Christendom at least, and would enter into the calculations and investigations necessary to show *how* this reduction of freight was to be effected, and *why* barges of 150 tons were so much less efficient than vessels of 800 to 1200 tons. But, in place of this, the public have heard nothing beyond such vague assertions as, that "the St. Lawrence is the natural outlet" for the "boundless trade" of the "far west;" if the Erie canal, with its pitiful craft of 50 tons burden—omitting all mention, or more probably ignorant of its small cost and low tolls—has yielded such large returns to the state of New York, what may not be expected from the "ship canals" of Canada, when "sea-going" vessels shall "float on Ontario and Erie," the Welland *schooner* canal connecting these lakes to the contrary notwithstanding—and innumerable other equally preposterous views and bombastic expressions, which are only too likely to prove as ruinous as they are ridiculous.

Yet this little Erie canal, which the State of New York has been endeavouring to enlarge to a size somewhat greater than that of the—according to Canadian ideas—little Lachine canal, and on which she has thrown away £3,000,000, is now admitted to be equal to any trade which can be expected, though there is no St. Lawrence to distance all competition for the down freight, no Rideau to compete with for the up freight, and although it enjoys a monopoly of *all* western freight, the people of New York not being permitted to use the railways along side of this canal on any terms—not even in winter—for the transportation of freight. These railways are owned by private companies, the government dreads their competition, and not without reason. For instance, flour is carried from Albany to Boston for 1*s* 6*d*. sterling per barrel, a distance of 200 miles by railway, through, or rather across, a mountainous country, or at the rate of ·09*d*. st. per barrel per mile, in small quantities (in full loads for 1*s*.); the rates from Buffalo to Albany, 363 miles, average 3*s*. 3*d*. st. per barrel of flour, or ·107*d*. st. per mile = 16 per cent. more than the highest charge on the Western Railway of Massachusetts. This latter is a private work, open throughout the year, and without any monopoly; the Erie canal is a State (government) work, closed between 4 and 5 months every year, and sustained by a monopoly unparalleled on either side of the Atlantic. The enlargement of this canal is postponed indefinitely, and a direct tax on every species of property in the State has been laid, to meet the interest of the money squandered on this and other legislative engineering follies, pointed out in Vol. III. (p. 122 *et seq.*)

Without stopping to inquire how soon this course will become necessary in Canada, I will ask, what intelligent Canadian or Englishman, who has visited New York and Canada, will for a moment tolerate the idea, that the trade of the latter country is likely to require, not equal, but ten times greater accommodation than that of New York? Should the trade of the St. Lawrence, twenty years hence, equal that of the Erie canal at this time, it will show an increase unequalled in the annals of this country. Look at the most, if not the only, successful work in Canada, the Champlain and St. Lawrence Railway, 15 miles long, and which cost not quite £40,000 sterling, on which 50 per cent. has been paid to the stockholders during the last six years, *because* the capital was small, and the outlay made with some reference to income. Had this been made with three or four tracks, on the scale of the Great Western Railway, it would have been as profitable to the stockholders as the St. Lawrence canals are likely to prove to the Province. One mile and a quarter of the Cornwall canal has cost as much as the 15 miles of railway, including cars, engines, buildings, wharfs, and steam forage-boat of 300 tons, whilst the income bids fair to be inversely as the cost: a fair illustration of the mode of conducting public works by private companies, as compared with that generally pursued in New York and Canada, where the helm is only too often in the hands of political adventurers and desperate speculators, who, having every thing to gain by governmental extravagance, naturally employ kindred spirits to execute their designs, which are, usually, the expenditures of large sums in certain districts, without any regard to the wants or interests of the community.

The gross receipts on the Erie canal for 1840, were 1,597,334 dollars = £330,028 st., and the present year will yield about the same amount. Assuming the St. Lawrence canal to be about one-ninth the length of this canal, and supposing the same business, the receipts would be very nearly £50,000 cy., on an estimated expenditure of £1,045,074 cy. as per Mr. Killaly's memorandum of 12th Aug. 1840, in which occurs the only argument (!) vouchsafed to the community for the necessity of this additional accommodation to the trade at such enormous cost.[1]

On the Erie canal the up freight or merchandize yields only one-fourth of

[1] The following choice *morceau*—the style of which is worthy of the reasoning—is all I have been able to discover.

"General Observations. The necessity of involving the province in the cost of forming a second water communication with tide-water, has been for a long time the subject of dispute and argument with many. Among the number of those who doubted the prudence of it, I was one until latterly; but the vastly increasing trade, *doubling almost annually*, and the conviction upon my mind, after mature consideration, that the lowering of freight consequent upon affording additional facilities, together with the productiveness of the western countries, which are only now coming into operation, will increase still further this trade *to an almost inconceivable extent*, have convinced me that a second and more facile outlet is called for. Besides the transport being confined to the Rideau, the navigation of which depends upon the stability of dams of great height, (in one case 60 feet,) should any injury arise to one of these dams, (as was apprehended last spring, either through accident or malice, the effects of it would be ruinous to half the commercial interests of the country.

"I am decidedly of opinion, that the scale upon which the Cornwall canal was undertaken, was unsuited to the means of the province, and was not absolutely necessary for the greatest increase of trade, which the most sanguine may look forward to; and that a schooner navigation, combined with a system of tug-boats would have answered every commercial purpose; but now, from the large expenditure already incurred upon the central portion, *the little required to complete it*, and the comparatively small saving that might be effected upon *what remains to be done*, by adopting the schooner scale, I am led to conclude that the best and easiest course will be to open the St. Lawrence throughout from Montreal to Lake Ontario for steamboats and schooners—not upon the *full size* of the Cornwall canal, but on a scale sufficiently large to admit a powerful class of steamers or tug-boats to pass." (Memorandum, 12th Aug., 1840, p. 5.)

It is scarcely necessary to say, that the "doubling almost annually" is bombast to an almost inconceivable extent; that "the small saving" is no less than on 28 miles out of 40, and the diminution consists in reducing the canal from 110 to 120 feet in width, and the locks from 200 by 55 to 200 by 45—a distinction without a difference you will say.

the income; on the St. Lawrence, the ratio is much more unfavourable, probably not less than 8 or 10 to 1, as the Western States, which furnish the flour and pork for the Montreal market, receive their merchandize exclusively by way of New York and the Erie canal; hence the greater the exports or down freight *via* the St. Lawrence, the greater the imports or up freight *via* the Erie Canal. But the down freight for Montreal will, practically speaking, all go by the river; hence £8,000 to £10,000 gross income would be a high estimate for the up freight of the St. Lawrence, if charging the same tolls as on the Erie canal, or four times that income at the present rates of the Lachine canal. Some little income will also be derived from the occasional passage of the steam-tugs employed to tow barges between the different sections of the canal. It will be observed that this calculation supposes the trade equal to that of the Erie canal, and that the estimates are entitled to confidence. The difference in the former is such as to forbid comparison, and the mere dimensions of the Beauharnois canal, given in the beginning of this paper, will be quite sufficient to show the inaccuracy of the latter—to say nothing of the actual cost of the Cornwall canal, built principally under the superintendence of the able resident engineer of the Beauharnois canal.[2]

It is quite unnecessary to point out the improbability of vessels of 600 800, or 1000 tons or larger steamers competing with barges of 150 tons drawn by horses on the canals, and by steam or wind, as at present, on the river between these canals; but, when we find that the latter craft can descend the St. Lawrence (without paying tolls) with seven-eighths of the freight, and that a suitable canal for the ascending trade would cost about one-fourth as much as the "ship canal," and be more efficient too, we are led to conclude that the whole affair would do no discredit to the "par excellence" land of jobs itself—the "sister island." The enlargement of the Lachine canal is about to be undertaken the coming winter, estimated cost £225,300 currency; and how this measure is to reduce the enormous tolls of that canal, which have already forced the trade to try the river, and successfully too, is a question not to be answered—in the affirmative, at least. The greatest possible reduction in freight I consider to be 6*d.* per barrel of flour, an amount quite insufficient to increase the demand in England, the very source of this trade, whilst freights from Montreal vary during the season not less than 2*s.* sterling per barrel, according to circumstances; a vastly more important consideration than any diminution which can be even anticipated between Montreal and Kingston. (The last Montreal quotations were 6*s.* sterling, from New York 1*s.* 6*d.* sterling, per barrel of flour.)

The Toronto paper, accompanying this, gives very fairly the general view taken by the entire agricultural and no small part of the commercial community; and, in confirmation, I will add, that by none did I hear the idea of using the canals for down freight ridiculed so much, as by French members of parliament, whose knowledge of the capacity of the river is nearly equal to that of the forwarders themselves.

A variety of other important facts might be adduced and different means taken; among the rest, the amount of business necessary to clear expenses and interest; and the amount of income which the present trade would yield; also the quantity of freight from western states seeking the New York market *via* the Erie, or Welland and Erie Canal.[3]

[2] The respectable British and American engineers who are, have been, or may be employed by the Board of Works, must not be confounded with the Board proper. They have merely to execute what their superiors, as politicians and intriguers, but their inferiors as men and engineers, are pleased to direct, and have nothing to do with the projecting of the works, as will be easily believed.

[3] Taking the interest and expenses at £60,000 currency, and the toll at 3*d.* currency per barrel of flour, it would require 4,800,000 barrels, about 7 times the present trade, to furnish the income, if even this comparatively moderate toll would induce boats to use the canals, and if the estimates of cost are correct. Besides the toll on the freight, the *boat* pays 1*l.* toll, and 12*s.* for towing through the nine miles of the Lachine canal, which for the 40 miles of canal would cost more than insurance and pilotage from Kingston to Montreal. The insurance is three-eighths of 1*d.* per pound; the pilotage about 2*l.* per 1000 barrels.

Allowing 30 minutes for passing one lock, and the entire present annual downward trade would pass through the Cornwall canal in 24 hours—the up trade before dinner, or at a point before breakfast. The river is equal to millions of tons per day, and the vast saving of time—already important between Lachine and Montreal—is an inseparable argument against the canals for the *down* trade—in other words, for *the* trade. The earlier and later navigation in spring and autumn is also important.

The Welland canal cost up to August, 1841, £491,777 currency, and requires, by estimate, £450,000 to complete it. (Memorandum, 12th August, 1841, p. 3.) The income for the last three years, has been about £25,000 currency, Mr. Killaly's "doubling almost annually an inconceivable extent" to the contrary, notwithstanding. The principal part of this is from down-freight, and a part also from American trade. With a navigation equal to that of the St. Lawrence, the income would be about £6000. Its principal hope of success rests on its becoming an American thoroughfare, which I think it eventually will be, for reasons given in my paper on "the spring trade" in the American *Railroad Journal* of April 15th, 1842.

Vessels drawing 12 to 14 feet water are brought with difficulty up to Montreal; and as for taking "ships" through 500 feet lockage up to Lake Erie, it will be at once obvious to the readers of the *Journal*, who have any acquaintance with inland navigation, that such views can be entertained only by those who are ignorant of the cost, weight and awkwardness of ships in canals. Should the trade become great, it is clear that the transhipment will take place at Quebec.

However new these statements of business may be to many of your readers—and obviously indispensable as they are to a correct understanding of the wants of the trade of the St. Lawrence—I believe they will be quite as new to the Canadian Board of Works, supposing that a Journal advocating such principles as this should accidentally meet their eye.

It was remarked, by the President of the Institution, (I think,) that many of the young engineers of England must necessarily look to the colonies for employment, hence the state and prospects of the profession in Canada cannot be received with indifference by British engineers in general; and it is on this account that I think the course of the Canadian government should not escape the scrutiny of the leading members of the Institution in London.

The honour and advancement of the colony and of the profession, as far as public works are concerned, must be considered as the same; and it is hard to say whether the Canadian Board of Works are doing more to injure the trade of the country, to degrade the engineer, or to effectually extinguish in Canada, that vital principle of British institutions—private enterprise.

I am, Sir,

Your obedient servant,

New York, 30th Nov., 1842. W. R. CASEY.

THE EDUCATION OF AN ENGINEER.

To which is added a few remarks bearing on the prospects of Engineering and its Disciples.

By H. F. CLIFFORD.

OUR estimate of the value of any scientific pursuit, consists chiefly in the degree of importance we assign to the amount and nature of the several qualifications due to its proper attainment. When we reflect upon the characteristics of engineering, we are not long in discovering it to be a science requiring much deep and intellectual study, assisted by steady perseverance, long and unceasing application to arrive at a just appreciation of all those practical data which experience can alone furnish, and impress vividly on the mind: one in which the laborious duties of the artisan must be blended with the sound theories of the refined mathematician, one, in fact, embodying the perfect union of theory with practice; but to define engineering in the full sense of the word, would be an endless task, for in that single word is comprehended a general knowledge of all the artifices that human ingenuity can devise to supply the conveniences of the present advanced and rapidly progressing state of civilization. This definition may, indeed, appear vague to some; but when we are informed of the vast grasp it takes of all those sciences which require no ordinary mind to cultivate and condense for the purpose of obtaining a thorough comprehension of the numerous ramifications of so noble and deeply interesting a study, we cannot be called presumptuous in placing it second to few, if any of our standard professions. Since, however, engineering as a comprehensive and distinct science has become fully recognised, and taken up its full position high in the rank of secular callings, there must have been long felt a growing deficiency of some fixed laws or definite principles to guide such individuals as were desirous of attaching themselves to the profession as a means of support, in obtaining a thoroughly useful knowledge of the subject. It is not our intention to throw any unreasonable objections in the path of the young aspirant to engineering fame, but we would seriously urge on his attention the necessity of engendering at the onset a firm and unchangeable resolution to encounter numerous and severe difficulties; but to be forewarned is to be pre-armed, and in the following remarks, which are the substance of a few years' careful observation, we have endeavoured to point out the general features of such a course of probationary study as from experience we have great confidence in recommending for adoption; being fully persuaded, moreover, that the only way to render engineering ultimately serviceable, at least in a pecuniary point of view, is to effect the happy combination of the practical with the civil department. For it is almost chimerical, now-a-days, for any person to imagine he will ever succeed solely in the capacity of a "Civil Engineer," inasmuch as civil engineering is a profession commanding but a very limited practice, and that what practice there is must inevitably fall to the lot of men whose public works have already earned for them an undying name, and with whose lives it will perish as a distinct avocation. Neither, on the other hand, can we recommend any one to pursue practical engineering alone, that is the business of an engine builder, for it is one requiring large capital to erect workshops and supply them with the necessary machinery: and moreover, there is not nor will there ever be now, a sufficient demand to employ all those first-rate works that have been established for many years, and whose name is a perfect guarantee for a good article. Again, owing to the slow but gradual development of the system of constructing manufactories on the continent, conducted by skilful Englishmen, there is every reason to believe that when the system arrives at a state of maturity, the foreign consumption of English machinery, especially locomotives, will be almost entirely annihilated. It is true, however, that there is a body of men, managers of large works, receiving no despicable salaries, and to a casual observer their occupation presents fair means of remuneration; but then what man is there accustomed to the usual comforts of life who would sink the better part of his early life in a workshop, as would be necessary to fulfil creditably such a situation? No. Such offices are chiefly held by men who, originally of the better class of mechanics, have gradually raised themselves above the level of their brethren by the exhibition of no ordinary talents, and have thus become entitled to the appointments as being the fittest parties from the nature of their previous education and intercourse with men whose habits and discipline they are best able to appreciate and to govern. With these few useful premises we now proceed to show the requisite functions to qualify a man to act successfully as an engineer. Let it be ascertained, as early as possible, that the person in question intends becoming an engineer, for having determined this important point, no time will be lost in acquiring any information foreign to the purpose. Latin and Greek must be entirely eschewed, and in the earlier portion of the student's career, let him obtain a tolerably clear knowledge of geography, history, arithmetic, English, French and German, the rudiments of ornamental drawing, sketching, the first three books of Euclid and Algebra. The consideration of the above will possibly occupy the student's attention up to the age of fourteen. From fourteen to sixteen finish Euclid; take up practical geometry and the higher parts of algebra—read plane trigonometry, conic sections, mechanics, hydrostatics, and hydrodynamics, the differential and integral calculus, and in order to connect more firmly together the links of this mathematical chain, work numerous problems involving each and all of the several branches. The elements of geology and chemistry, and such other parts in detail as bear more immediately upon civil engineering have great claims on the pupil, whilst a strict attention should be given to mechanical drawing, sketching, linear, and isometrical perspective, with the theory of shadows. During this period, likewise, the student should make a practical investigation of surveying, and learn to use, with ease aad accuracy, the level and theodolite, to make himself acquainted with the general principles of architecture: and, in order to prepare his mind more fully for the reception of its future tenant, peruse some standard elementary work on engineering.

Having completed his sixteenth year, and assiduously devoted all his energy to the investigation of the foregoing subjects, let the embryo engineer be now placed in some first-rate manufactory, where there is a great variety of work executed, for a space of not less than three years. We repeat, *first-rate* manufactory, for as his standard of judgment of mechanical productions will be formed in a great measure by the quality of work passing under his notice during this time, it is proper he should connect himself with one of the highest repute. Here he will lay up an ample store of solid information regarding land, marine, snd locomotive engines, mill-wright work, and, in fact, machinery in general. But this information, we can assure him, is not to be purchased in the character of an on-looker. He must keep the same hours as his fellow workmen (*pro tempore stante*); he must exchange his ordinary attire for the fustian suit, the drawing room and easy chair for the workshop and the vice, and go through the various gradations of the service till he is found competent to undertake some responsible situation over the workmen. And it is a well known fact, that it is impossible for a man to pass a correct and conscientious opinion with regard to the execution of any mechanical work, unless the individual in question has himself gone through a regular system of practical application. It is true the beginner, unused to the rough habits of a workshop, and unaccustomed to associate with such characters of men as he finds there, will have to contend with many inconveniences and annoyances, but then he must make up his mind to wield the hammer, chisel, and file, with a firm determination to overcome all difficulties. We admit it requires a strong and persevering resolution, and many are they, beginning with a good heart but meeting with impediments at the commencement, have shrunk from the prosecution of a course of training, which, pursued to completion, would have amply repaid them the extra exertion due to its attainment. Locomotive building claims especial care for its subsequent utility, and let it be a leading principle throughout the entire course, to ascertain correctly and set a due value upon the proportionate strength[1] and properties of materials in general, that the engineer may be able to adapt with confidence such invaluable knowledge when he may hereafter find it available. For the *requisite* strength is alike conducive to symmetry of figure and economy of material—an intimate acquaintance with the relative functions of the various descriptions of water wheels[2] is indispensable to the engineer, on account of the great utility and *economy* of such power in countries and districts where water abounds, and where it would be both inconvenient and expensive to erect steam engines and their concomitant paraphernalia. The foundry must likewise have its due share of importance, and the student should contrive to obtain an introduction to some large iron works. Here he could devote a short period to analyzing the processes of smelting, puddling, casting and forging, and thus render himself capable of passing a good judgment on the quality of malleable and cast iron, when coming under his notice for engineering purposes on future occasions. Although mining engineering is reckoned a distinct branch, and requires long experience underground as a viewer to sustain any responsible situation, still a short time passed in investigating colliery work in some well regulated coal pit, would make the pupil acquainted with much valuable information concerning pumping engines, and the general routine of the mechanical department, as would be of material service to him. During his residence at the manufactory, practice in drawing should be kept up by periodical visits to the drawing office, and he should endeavour, on all occasions, to procure for himself copies or tracings of any useful piece of mechanism, and thus, by carrying the principle out in time, amass a series of practical illustrations of invaluable use in after life. Lastly, in order to render the former part of his education ultimately serviceable, the pupil should, during the evenings after work hours, peruse attentively such works as treat more immediately on subjects forming the constituent elements of his profession, and for the purpose of blending amusement with instruction, we could suggest reading at his more leisure hours, and thus keep pace with the constant improvements, the best periodicals that treat practically and theoretically of civil and mechanical engineering. Having completed the first grand epoch in the probationary regime, the pupil may easily refresh himself with the pleasing intelligence, that the remainder of his duties are comparatively easy to the ordeal he has already passed through. The next step is to place himself under the direction of an eminent civil engineer, who has railways and other works connected with this department of engineering under his superintendence in course of construction. In this new state of things, the pupil should strive hard to obtain some inferior, but by all means *active and responsible*, station, for there never is that care and attention bestowed on any object that is simply dependent on *our own* caprice. The pupil should, therefore, consider it a matter of paramount importance to endeavour sedulously to create a high confidence in his own and his superior's mind, that may lead, as soon as possible, to his entrustment with some minor office, the creditable discharge of which depends entirely on his own exertions. For confidence, let it be understood, is the capability of expressing a decided and correct opinion with regard to any question that may arise, and which can only be given in cases where a thorough comprehension by *experience* of the details of the point at issue is positively entertained. With civil engineering commences a new era. Railway making, with its surveying, leveling, cutting and embanking, bridge building, drainage and other works, will serve to keep the mind continually employed, in order to become well versed in all its minutiæ. The building of harbours, docks and light houses, the formation of canals, will severally claim a proportionate degree of careful consideration. Common road-making, warming and ventilating, general principles of carpentry and masonry, with a train of minor but no less useful qualifications, will in due order require each its own peculiar study: lastly a real concise method of making estimates and getting up specifications for contract works, will be found of great utility; the former can only be obtained by ascertaining on all occasions the prices of every description of materials for engineering purposes in the different localities, the latter by continual reference to specifications of works already executed. Here, then, is a broad field open to the successful practice of acquired knowledge, whilst design and construction present favourable opportunities for the display of any talents or ingenuity the young engineer may be fortunate enough to possess. To acquire a sound knowledge of the strength and properties of wood, stone, and iron, should be considered a matter of the utmost importance, and a few months could be profitably passed in an architect's office of good repute. We have mentioned the preceding qualifications *en masse*, but they should be carefully and discriminately adjusted to the age, ability, and progress of the student. Let the different subjects be presented to his notice in their most elementary shapes at the onset, that the rudiments of one and all may be indelibly fixed on the mind: for then the intellectual faculties having mastered the approaches, will grasp with a firmer hold upon maturer development the more complicated facts. And it should not be lost sight of, that the amount of information acquired, depends almost entirely upon the youth's own assiduity, as he will not find persons continually at his elbow, as in the schoolroom, either urging him on or threatening him with punishment for neglect of duty. He must see

[1] By proportionate strength we mean the relative strength the several parts of any piece of mechanism should bear to one another.—Tredgold, Barlow, &c.

[2] Smeaton's experiments.

clearly it is to his *own interest* to make the best possible use of his time. It is not within the limits of an article for a Journal, to enter more fully into detail, but we have endeavoured in as brief a manner as consistent with the nature and magnitude of the subject, to draw the outline of a plan of education, that from *actual* trial, we can seriously recommend for adoption. We would fain conclude here, but cannot resist making a few passing remarks on the several schools for engineers that have lately sprung into existence. However radically good the principles and intentions of any establishment may be, professing to teach a young man engineering, however well such principles may be carried out and matured by able and efficient masters, they will fall immeasurably short of their purpose, when compared with the preceding course. For it is not within the limits of a school-room education, to convey that inestimable practical knowledge, which can only be acquired by constant every day association with bodies of men, whose daily bread is earned with the sweat of their brow, and who can readily and satisfactorily explain any questions or doubts that may arise connected with their individual trades. The latter course may, indeed, materially assist the embryo engineer in the earlier part of his career; but having arrived at a suitable age, the workshop, and then the open field, from the staking out of the railway to the laying of the permanent rails, will be found far more congenial to the spirit and practice of engineering. In conclusion, it is our decided opinion, that an individual educated according to our method, and possessing, in a fair degree, all the advantages arising from it, will be fully competent, at the expiration of his articles, to undertake some responsible and remunerating situation; and it is not too much to anticipate, that if he be an industrious and persevering character, he will materially benefit any works with which he may become connected, and with good natural talents, assisted by standard ability, he may possibly shine forth a bright star in the wide sphere of a distinguished profession; and should he not be fortunate enough to rival the memories of Brindley, Smeaton, Telford, Watt, Stephenson or Brunel, he may perhaps leave behind him lasting monuments of his skill, that would do credit to his more illustrious and deservedly renowed predecessors.

Now for a few words bearing on the prospects of engineering, and its disciples. When we review the statistics of railways, and reflect upon the enormous quantity of money (£70 000,000) expended by private individuals on such speculations, within the limited period of railway existence—when we consider the little return such parties have had for their invested capital up to the present time, the heavy loans several companies have still to pay off, notwithstanding the fallacious exhibition of prosperity, in the declaration of a moderate dividend to the shareholders—when, moreover, we consider the ruinous state of trade, the prevalence of distress, the sluggish circulation of specie this last two or three years, caused by the diffidence of large money holders to let it change hands—and when, lastly, we contrast the superabundant supply of engineering skill compared with the demand, we cannot feel surprised taking full cognizance of the above, and many other contingent circumstances, at finding engineering in the unpromising condition it has presented of late. It is now generally admitted, that profuse expenditure has been the prevailing feature of railways hitherto constructed; and it should be the aim of future companies to complete their engagements with as much economy as is consistent with the durability and magnitude of the undertaking. We do not object, let it be understood, to additional expense being bestowed on the great arteries diverging from the metropolis, for such may be looked upon as public works, and have a reputation to hold up; but the smaller veins branching from the main trunks, should be made at as little cost as possible. Once let a right spirit of economy be established between the directors of railways and their engineer, and we shall soon have public confidence restored, and a new impulse given to the profession. There are many lines that must be laid out and finished, to render the ramifications of the system complete in England. The grand link connecting Scotland—will there not be two?—is yet wanting in the chain. Ireland is as yet untouched—would not a good system of internal locomotive communication go a long way to improve the civilization and better the condition of that unhappy and distressed country? This would be, indeed, desirable, if only for its moral and social effect. And is not her soil as capable of sustaining rails, and yielding profit too, as any other land? And we do think that, could the government overcome its present difficulties, and improve the revenue, it would do well to assist a spirited public in their meritorious desire to form a thorough railway connection throughout the entire kingdom, at least in such cases as presented ostensible means of remuneration for invested capital. It is true the public were too prone to believe, at the commencement of the railway mania, that in committing their money to the coffers of the company, it was to be multiplied to the unwarrantable height of their expectation; but their too sanguine anticipations were disappointed, and sad experience begat caution—we hope not discouragment; for it was not likely, upon contemplation, that an impetuous torrent, the characteristic of early railway speculation, bursting from its source, could dash on in its headlong course without meeting, at no very remote period, with some counteracting agency—some impediment to its success.

Now, when we meditate on the crowded state of the avenues to all descriptions of avocations for the last few years, we cannot feel astonished that, upon the introduction of a comparatively new profession, as engineering, public attention should be diverted into a fresh channel, and seize with avidity upon one holding out such promising advantages. At this period, too, there were comparatively very few men who had been really trained to the profession; numbers, however, upon ascertaining the necessary qualifications, went vigorously to work—but then time was an essential requisite to collect *materiel*; and in the interim a body of men, termed surveyors, possessing a tolerably good knowledge of their business, with a smattering of a few properties bearing some analogy to this branch of engineering, availed themselves of the opportunity, managed to get employed (for want of better substitutes) in some inferior capacity at first, until gradually acquainting themselves with a few of the details, arrogated to themselves the term of "Civil Engineers;" and before the genuine pupil had matured his education, these men had obtained, and do now hold, several of the best situations in the service. This incident will doubtless explain why there have been, and are, so many intelligent articled pupils out of employment; and it is a known fact that many have left the profession, their patience quite exhausted. Again, did the younger scion of a respectable family, in the innocence of boyish delight, sketch *anything* resembling a steam-engine, the anxious parent felt persuaded "the boy was a genius," and only required to be educated as an engineer to develop extraordinary talent. A great number of these geniuses, however, soon finding that engineering to be properly understood was no easy matter, floundered on for awhile, and at length gave it up as a hopeless business. Nevertheless there were many, having endured much tribulation, passed the rubicon, and thus swelled the numerical strength of the profession. It would appear, therefore, from the preceding analysis, that whilst the demand was falling off, the supply of *bona fide* engineers and self-entitled adventurers were increasing in a formidable ratio. The present aspect is, consequently, gloomy enough; but there is this satisfaction, if it be any, that, being at the bottom of the wheel, the next change will, in all likelihood, brighten the prospect. Upon reviewing the system of railway policy abroad, we cannot but advise the matured pupil to strive hard for employment at home before seeking it elsewhere; for Englishmen are not treated on the continent with that good feeling and generous acknowledgment of their worthiness to which they are justly entitled. There is likewise much jealousy existing amongst the French, and it almost invariably happens that such English engineers as have been led by promising hopes to enter into engagements have, upon a short trial of their continental neighbours, found their position so unpleasant as to cause resignation of office, if possible, and in default of that, to put up with much unmerited insolence, or have been unceremoniously discharged at the immediate expiration of the articles of agreement, but not before their wily superiors (in office, not abilities) have taken good care to reap a rich harvest of experimental knowledge from the solid acquirements of their *employés*. Many there are too, wearied with long inactivity, and despairing of obtaining situations in their own country have turned their attention to colonial prospects. But here, we fear, they will fall far short of their expectations; for the present condition of our colonies is not of that settled or flourishing nature as to favour the designs of the accomplished engineer. The fact is, a country must be in a tolerably advanced state of civilization—must possess extended commerce, internal trade—must have substantial resources of ITS OWN, and contain a strong body of capitalists devoted to the execution of public work, before it can be pronounced in a fit state to admit of engineering operations with any hope of success.

It is true a few *surveyors* may meet with encouragement in the more recent settlements of New Zealand and thereabouts, to head the exploring staffs in plotting out the ground for future emigrants, and there is no doubt of the existence of certain districts in America (especially the more southern parts) where the mechanical department might be carried on to a very profitable extent. But then what man is there, without some very definite plans for, and sure prospect of speedy success, a voluntary exile from father-land, and the comforts of home, with all its cherished attractions, could embark his living in such truly *outlandish* speculations. What are we to do then, is the general and anxious inquiry. Wait patiently, till the tide of fortune takes a more favourable turn, which we hope is not far distant. There is much left to be done in old England; and could the country once again recover from the depressed state, under which withering influence it has so long laboured, there is no doubt that engineering, like all other avocations, will quickly resume its former activity, and then every properly constituted member of the profession will meet with his due share of employment.

AN ARTESIAN WELL IN THE SEA.—An attempt is now being made at Brighton, to obtain water from beneath the chalk under the sea. The operations for this purpose are being carried on at the head of the chain pier, and it is confidently expected that the strata of chalk at this spot does not exceed 70 feet in thickness, through which, on arriving at the green sand, a constant unfailing supply of pure water is anticipated.

ROYAL ACADEMY.

Professor Cockerell's Lectures on Architecture.

(From the Athenæum.)

The Professor began by quoting the regulation of the Royal Academy as to the Lectures on Architecture—"That the Professor shall read annually six public lectures, calculated to form the taste of the students, to instruct them in the laws and principles of composition, to point out to them the beauties and faults of celebrated productions, to fit them for an unprejudiced study of books on the art, and for a critical examination of structures." It is understood that these lectures were to be given by a Professor in the full practice of his profession, according to the dictum of Vitruvius, "that it is the union of the practice with the theory, that makes the sound architect"; and although he felt that it was precisely this circumstance that gave all the value in the eyes of the students to these lectures, yet it was obvious that in the midst of the distractions and bustle of professional practice, the Professor laboured under great disadvantages. It was much to be desired that the means at the disposal of the Royal Academy could enable it to extend these lectures according to the model of the French Academy, which, on architecture alone, had established five classes, each having a separate professor,—namely, 1, Theory; 2, History; 3, Mathematics; 4, Stereotomy and Construction (in which important class two *Repetiteurs* were appointed); 5, Perspective. Such liberal instruction secured the honour of the profession, and protected the public against empirical practice; and gave the French architects, in particular, that advantage in foreign countries, which the unassisted genius, perseverance, and enterprise of our own countrymen found it difficult to contend with. Aware of this mortifying inferiority in our public education, the students would exert themselves so much the more in their private studies to supply the deficiency, and would learn from this well digested system the course they should pursue. This Academy had, indeed, been founded by an illustrious prince (George III), and great were the obligations of the arts and the public to his memory; but the means by which it existed were of its own creation, and those means were barely sufficient to fulfil its engagement, to support gratuitously the only school of art which this country possessed.

It is an axiom with the civilized nations of the Continent, that the fine arts are eminently calculated to increase human happiness and exalt human character, and greatly contribute to the reputation as well as the real interest of a country, especially of a manufacturing country.

But the austere government of England makes the fine arts no part of its glory, its policy, or of its expense. And were it not for the sympathy and patronage of the public, even this limited institution could not exist; nor would the country escape the reproach of the Celestials of "outer barbarism." The fine arts have, indeed, the countenance of the supreme head, and of "the powers that be"—the Ministers of the day, who cannot, as gentlemen, renounce the attribute of taste; but they have uniformly shown by their public conduct, that they do not consider its support amongst the people a political duty.

It is now more than a hundred years that Thomson, the best informed upon the arts of all our poets, indignantly remonstrated on our national inferiority and neglect of this branch of intellectual culture, and complained with grief, in his Ode to Liberty—

> "That finer arts (save what the Muse has sung,
> In daring flight above all modern wing,)
> Neglected droop their head."

Foreigners have attributed this disregard of the rulers of an ingenious and a great people to various causes—to physical insensibility, to the sordid nature of our commercial habits, or the adverse propensity of the Protestant religion—to which objections the history of the ancient dynasties of this country (never inferior in the fine arts), the abundant enthusiasm of individual artists of our own times, and the public sympathy, are direct contradictions. Finally, they have fixed the reproach on the government, by pointing at the Schools of Design established by parliament; for they say, truly, that so soon as the inferiority of our design in manufactures drove us from the foreign markets, we took the alarm, and immediately formed schools of design, *à l'instar* of those on the continent; not from a generous love of art, but, confessedly, from the well-grounded fear of loss in trade. The members of this Academy hailed the measure with joy, as the harbinger of a better sense of what is due to our intellectual position in Europe, and they have willingly given their gratuitous attention to its conduct. But the instruction of youth must be accompanied with the higher prospect of employment and honour in national works; and we are happy in the reflection that the decoration of the parliamentary palace at Westminster, and the interest taken by an illustrious personage in that great object, hold out to us the hopes of equality at least in these noble studies with the improving countries of the continent, and the opening of a new career for genius and industry.

But an erroneous and mischievous scepticism as to the utility of Academies of fine art altogether, has long been fashionable, which has not, however, been applied to others, for no one has ever yet despaired because a Newton or a Locke are not annually produced from Cambridge and Oxford; but of these it has been plausibly said, that no Michael Angelos, Raphaels, or Palladios have been produced by them since their foundation in the 17th century; it is forgotten, however, that the patronage and immense employment which elicited the talents of those masters, have also been wanting; and that without the field for their development, and all the expensive machinery by which they can be brought to bear, Academies can do little more than preserve and transmit the rudiments of art.

Fleets and armies are necessary for war, and without these the greatest captain of his day might have been nothing more than an eminent professor at Sandhurst.

Academies were established as depositories of learning and practice in the fine arts, and the means of their preservation and transmission through the vicissitudes of the times. The enlightened and commercial Colbert had seen how in Greece and ancient Rome, and in modern Rome, under his own countryman, the Constable Bourbon, a public calamity might disperse and ruin them for half a century, without some fixed and corporate body and abode. He never dreamt that, in the absence of the fostering patronage and employment of government, the Academy could do more than fulfil these negative objects. The Royal Academy had done much more than this—it had sustained the credit of the country in fine art, and had reared talents which were now part and parcel of English history. Through good and evil report it had nourished the flame; and it was consolatory to find that they had transmitted it to better times, through long and adverse circumstances; for now they had the happiness to see two Professors in the Universities of London, the British Institute of Architects, large public patronage in Art-Unions, &c., and a growing interest in the Universities of Oxford and Cambridge towards fine art generally.

But Architecture, as a science dignified by an intimate connexion with the exact sciences, and by her acquaintance with those eternal laws of mathematics and of physics which are obeyed throughout the universe, was, in this Academy, regarded only as a fine art, and these lectures were designed to illustrate Architecture in that capacity alone. Dealing with the phenomena of beauty and ideality in the form and aspect of her contrivances, she becomes an essential member of the fine arts, the more essential since her conclusions are more undefined and remote than any other branches of the fine arts, save Poetry and Music, with whom her nearer relationship than with painting and sculpture, is sustained by many. But in all that respects the beauty of forms and their combinations, she must never forget her obligations to her sisters painting and sculpture, by whose aid alone she becomes the *ars regina*, and keeps in view her prototype, Nature, ever equally solicitous of beauty and of use. And the moment she declines their counsels, her proportions become anomalous, and she descends to the mere building art.

In Egypt, where painting and sculpture were in comparatively small esteem, and again in the middle ages, proportions were wholly capricious, and subject to no order or regularity; nor have any been ever attributed to them even by the greatest admirers of Egyptian or Gothic architecture. On the contrary, the Greeks, aided by the union of the three arts, soon established that analogy with the organized productions of nature, which fixed the proportions of architecture in so determinate a form as not to be safely departed from, and which, whether in the days of Phidias, or Raphael and Michael Angelo, or any other renowned period of art, has been approved and adopted as just and incontrovertible.

The fulfilment of the duty of the Professor under a limited number of lectures, had been a subject of some anxiety and difficulty. The history of the art was the only safe foundation of the study, and had, therefore, formed his first course. "Architecture," says Sir C. Wren, "is founded on the experience of all ages, promoted by the vast treasures of all the great monarchs, and the skill of the greatest artists and geometricians, every one emulating each other. And experiments in this kind being greatly expenceful and errors incorrigible, is the reason that architecture is now rather the study o antiquity than fancy." With respect to the duration and progress of this art, it might be said that a hundred years were but as a day; being made for ages, it could not, therefore, be subjected to the vicissitudes of fashion; and the slowness of its progress and invention ought to inspire us with respect for antiquity and the authority of example, and to repress that presumption which too often assumes to dispense with them.

In fact, at every epoch in which the art had raised itself to its highest conceptions, we find not only artists but theoricians, archæologists, and historians, occupied in describing its progress and inventions, illustrating its monuments, and seeking out its antiquities. There are many histories of architecture more or less complete; Canina's work promises to supply the history of ancient architecture which Winkelmann had left very insufficient. D'Agincourt's "Histoire de l'Art par ses Monumens" was an admirable work; it treated of the art from its decline to its revival and restoration. Durand's "Parallel des Edifices anciens et modernes," on the same scale, is highly illustrative of the history of architecture.

The second course (that of last year) had treated chiefly the literature of the art; following out the Academic instruction quoted above, namely, "to fit the students for an unprejudiced study of books in the art." It had been well said by a learned prelate, "that we do not live in an ignorant age, but certainly not in a learned one;" and it was painful to see those authors who had been canonized by ages, either attacked and discredited, as Vitruvius, or held to be antiquated and obsolete, as the old Italian and French authors, and above all, the admirable Alberti, the Bacon of the art, and others of the greatest interest. The obvious consequence was, that new lights, fashionable conceits, and heretical opinions, were conducting us into the large ocean of error. As well might the lawyer or the divine dispense with books as the architects. In the very dawn of literature the architect was required to be learned. In the Memorabilia of Xenophon, Socrates inquires, "But what employment do you intend to excel in, O Euthedemus, that you collect so many books? is it architecture? for this art, too, you will find no little knowledge necessary."

A familiar example of the great utility of these researches had been given in the quotation from Philibert de l'Orme (lib. ii. c. xi.), of the specification for concrete, written in the latter part of the sixteenth century, and corresponding precisely with the recent so-called discovery of this method of securing foundations. During the last century our architects had discontinued the ancient practice, having adopted the most fallacious fashion of wood-sleepers, to the ruin of many fine buildings. It was, then, the ignorance of this invaluable and most instructive and amusing author, Philibert de l'Orme, which had led to so fatal an error.

With reference to Vitruvius, the commentators, in forty-one editions, since his discovery in 1416, were shown to have made but slow progress, and to have done the author but little justice; and ever since the uncandid Schneider had published his edition in 1807, ten important discoveries, illustrating the correctness of his theories, had been made by modern travellers and architects.

In the present course the Professor purposed the consideration of the more difficult, but no less important, injunction of the Academic regulation, "that these lectures should be calculated to form the taste of the students, to instruct them in the laws and principles of composition, and fit them for a critical examination of structures."

Those laws and principles which are technical, were often treated, and were more obvious; but those which constituted architecture a fine art, were more subtle, but not less vital, to those who aspired to the higher attainments of the art, namely, the sublime and beautiful. Such inquiries had employed the most learned and ingenious minds in all ages; and although theories are proverbially dangerous things, and must be treated with great caution, yet, recommended as they are by the authority of great names, they ought to be known and discussed; effects attributable to right reason and right feeling are essentially subjects of discussion, and the old proverb should be reversed, and "De gustibus disputandum est" should apply to all those preferences which depend on reason, and not on sexual or fanciful arbitrament; and though the inquiries into the æsthetical of art, which have occupied the last century particularly, fall short of the results we should desire and expect, and that after all genius alone can rightly solve these questions, which elude common sense, yet we may cultivate and improve our critical powers, learn to think more accurately, and correct that colloquial laxity of speech which refers all impressions to some cant phrase of undefined signification, as *fine* and *beautiful*, *tasteless*, &c.

Such investigations afford the only means by which the principles of this or any other art can be ascertained, and the artist can be enabled to determine whether the beauty he creates is temporary or permanent, whether adapted to the accidental prejudices of his age or to the uniform constitution of the human mind; and whatever the science of criticism can afford for the improvement or correction of taste must altogether depend upon the previous knowledge of the nature and laws of this faculty.

In the following lectures the Professor proposes to review the examples cited in his former courses with reference to these important principles.

LECTURE II.

The Professor said, that the developement of the human faculties was exhibited in the history of Architecture under its most favourable aspect. The art might be termed the epitome of of civilization, the first fruits of social order and combination, of every discovery in science, and of every conception of beauty. Political history was of comparatively inferior interest, and betrayed, for the most part the depravity of our species. The natural labours of man, those of agriculture, or commerce, their unvarying succession, brief endurance, and disappointment, leave melancholy convictions; but in the occupation of architecture, man finds the employment of those higher aspirations and idealities for which he feels himself born, as well as of his physical energies. Here he perceives that he has a soul; all his loftier conceptions—order, calculation, beauty, and immortality—are opened to his contemplation, and he seems to feel the power of extending his works and his memory beyond the bounds of nature and of time.

The exhibition of these innate and physical capacities seems to be his natural desire; and the progress of his operations coincides with his intellectual growth. In his boyhood he contends with the forces of nature; he moulds the vast rocks, and rears on end the monolithic obelisk; or, accumulating the masses with laborious endurance in the pyramid, he emulates the works of Nature herself; and exulting in the force of order and combination, and his acquired skill, he exclaims, with the Babylonians, "Go to, let us build a city and a tower, whose top may reach unto the heavens, and let us make us a name." Add, although in our advanced civilization, we may smile at the superfluity of such labours, we must not forget that by them man first vindicated his capacities, and that metallurgy, mechanics, and all the manual exercise and discipline which fulfilled his apprenticeship to civilization, were brought into practice, which soon employed itself in more intrinsic benefits.

The age of Alexander and the Romans abundantly illustrated this truth. Man now contends with the elements. The ocean is curbed by his ports and quays, and Pharos; he sails across its bosom; marshes are drained; sewers, canals, aqueducts, and roads, exhibit the mastery he had acquired, and his conquests over nature. Frontinus, whose work on aqueducts was written about the year 80, has a passage remarkably illustrative of the growth of this spirit in his time. After giving a description of the nine aqueducts under his care, brought to Rome by successive labours, making an aggregate length of about 142 miles, he exclaims, "with so many waters, and so many magnificent works necessary for their transport to this great city, will you compare the idle Pyramids of Egypt, or even the inert works of the Greeks, however celebrated and glorious in his ory?" The ingenuity of the architect now, therefore, issues to use, and through 1800 years it is more or less subordinate to it, either in the great business of religious and moral improvement in the building of churches, or the security of civil life in castles and mansions. Finally, in recent times, it is contracted to absolute utilitarianism, and all its powers are bent to the perfection of the individual dwelling between party walls, in which every subject of the state is in the enjoyment of personal luxuries and conveniences of life unknown to the Pharoahs, the Medici, or the magnificent Louis the Fourteenth.

Thus, as Monsieur Guizot finely observes, each age and nation seems to have flourished for some beneficial purpose to Mankind, which, being accomplished, it disappears from the stage.

The history of architecture may be said to divide itself into five classes—Sacred, Civil, Military, Domestic, and Monumental. In the accompanying drawing (a roll about twelve feet square, containing a vast group of buildings inscribed within the outline of a pyramid, on a large scale) are seen indiscriminately some of the principal monuments of all these classes (except the military), comprising a period of 3,334 years. We may say to the students, in the words of Napoleon to his troops, before the Pryamids of Gizeh "Quarante siècles vous contemplent!"

This arrangement done under the Professor's direction, about twenty years ago, appeared, he believed, for the first time in the Penny Magazine. A comparative view of the great buildings of the earth, on the same scale, might minister to that false estimate of merit, which is derived from material dimension; but that criterion would vanish before the comparison of renown; and the Parthenon, and other small buildings, here represented, would abundantly illustrate the preference to be awarded to

The little body, but the mighty soul.

National attachment might excuse his pointing out the spire of Old St. Paul's, the only one exceeding the height of the Great Pyramid. Those of Mechlin and Cologne, though designed to have exceeded it, remained imperfect. A limit seems to be placed to man's arrogance and vain glory. We were taught, like the Babylonians, that the God of nature delights not in the accumulation of his favours and his light, and isolated in single spots, but in the wide-scattered communication of them throughout all lands.

But the observations already offered, were illustrated still further by the sections [on a roll as large as the former, showing the structure of the most important temples, on the same scale.] The issue of the art in use and economy, was most remarkably shown in the comparison of those sections, in which we observe, that St. Paul's displays the largest bulk with the least material, hitherto contrived.

He should now call the attention of the students to two rolls [about 16 feet long each], in the first of which the plans of the remarkable temples of the ancient world, from the Tabernacle in the Wilderness (1491 B.C.) to the reception of Christianity (313 A.C.), and in the second those from that epoch down to 1812, were all laid down to the same scale. There was displayed, as it were, the genealogy of temples, during 3330 years.

It was sacred architecture which he purposed to review cursorily that evening; and short enough was the time for a subject so deeply interesting; indeed, such an expression might be deemed presumptuous; and it was obvious that we should be enabled to do no more than pass the plans in review, and remark upon those characteristics which became the more palpable on the synoptic view of centuries and ideas of such extent and variety; and which were less frequently commented upon. It might be objected by the students that subjects of such vast scale and importance and rare occurrence should be illustrated, rather than the more practical; but we should remember the dictum of Vitruvius, that the architect ought to pursue his studies "maxime in ædibus Deorum, in quibus operum laudes et culpæ æternæ solent permanere." In fact, the remains of these precious exemplars of skill and cost and labour, the types of our art, were still discoverable even from the most remote times, as if Nature herself, as well as man, had respected them.

In approaching sacred architecture, and in discussing the technical considerations of the forms and structures of temples, we cannot but bow with respect and veneration to those motives and affections, the noblest of the human heart, which have ever urged these sacrifices to the mercy and the majesty of the Creator—and we recognize in the Grecian or the Druid, the Hindoo or the Christian temple, the universal sentiment so finely expressed in the Psalms, CXXIX:—

"Lord, remember David and all his trouble!

"How he sware unto the Lord, and vowed a vow unto the mighty God of Jacob,

"I will not come within the tabernacle of mine house, nor climb up into my bed,

"I will not suffer mine eyes to sleep, nor mine eyelid to slumber, neither the temples of my head to take any rest, "Until I find out a place for the temple of the Lord, an habitation for the mighty God of Jacob."

In excavating the foundations of the temple at Ægina, the remains of burnt woods and bones of sacrifices were discovered, mixed, no doubt, with libations and tears and aspirations as warm as those of David:—at Selinus we find the steps in front of one of the temples worn down almost to an inclined plane, by the feet of the devout. So again of the accomplishment of these vows amongst men of all ages and nations, we shall find the most solemn and full expression in the eighth chapter of the First Book of Kings, the dedication of the temple by Solomon.

The resemblance of the plan of the Tabernacle in the Wilderness, and with its surrounding court (the first in our series, B.C. 1491), and still more, of the temple of Solomon; with the arrangement of the Greek and Roman temple, down to the Antonines at the end of the second century of our era, is very remarkable. In the first the parallelogram is preceded by a portico of an irregular number, namely, of five columns. In the second (1012 B.C.) we have the temple in Antis.

If we enter into particulars, we are still more struck with their correspondence; we find for instance, the irregular number in the temple of Jupiter at Agrigentum, one of the largest and most important of antiquity: seven columns compose the front; and we are reminded of Solomon's saying, (Prov. ix.) "Wisdom has builded her house, she has hewn out her seven columns." Again, at Pœstum we have a temple (miscalled a basilica) with nine columns in the front. Other examples also might be cited. Again, of the Temple of Solomon, that of Themis at Rhamnus, and the frequent temple in Antis, with its pronaos and heiron, is the constant copy. The altar of sacrifice, that of incense, the laver, the table of shew-bread, are all traced either in existing remains, in bas-reliefs, or in medals.

The connexion of classic and sacred architecture is thus apparent; and the author of "The Plagiarisms of the Heathen Detected," (Mr. Wood, of Bath,) is borne out in this comparison of the *plan and arrangement* of temple architecture. The common error (and one to be carefully avoided) is the attempt to trace this resemblance in *the styles*, or the ichnographic figure of the parts and orders—the mere vesture of the scheme; and the failure in straining the texts and examples (Corinthian or Doric) to a perfect correspondence, either in Wood, Villalpandus, or his learned predecessor, Wilkins, has always thrown a doubt upon these interesting investigations; but the comparison of the *plans* makes the Tabernacle the type of the Greek and Roman temple, a work which Paul as well as Moses assures us was inspired by the Deity, "for see, saith he, that thou make all things according to the pattern showed thee in the mount." (Heb. viii.)

It is remarkable that the earlier or contemporary works of Egypt show no similar arrangement; nor was it likely that Moses should adopt and recommend any form associated with Egyptian recollections. The circular form of plan is indeed traced in Greece, and Rome more especially, and amongst the Druids, but the most frequent by far is the parallelogram, after the Tabernacle: in fact, the earliest inhabitants of the bordering countries were apparently monotheists; their connexion with the Jews through Tyre and Sidon, their respect for a people of superior knowledge and religious instruction, may well have sanctified their form with them: the ritual was the same with them; the idol took the place of the ark; with both, the temple was the Domus Dei; both were religions of sacrifice.

The ritual was thus the originator of the form of the temple, and must always be so. The temple in Antis became (with a view to ornament, and by the successive inventions for decorum and dignity) the prostyle, peripteral, dipteral, and pseudo-dipteral. The much-boasted beauty of the Greek temple was not, then, an invention of taste, but one of ritual; and in the consideration of templar architecture, in all times and countries, this important fact must be carefully borne in mind.

Another point of resemblance of classical and Jewish architecture, of great import, since it is the hinge upon which the whole system of ancient architecture turns, is the employment of "costly stones, even great stones, stones of ten cubits, stones of eight cubits." Upon this practice the whole character and taste of sacred and classical architecture depends. The tenth book of Vitruvius treats chiefly on large stones and their transport. The type of Domus Dei admitted of no extension; the only mode of giving magnificence and dignity to temples, thus circumscribed in form and composition, was by the employment of monolithic masses, and by the exquisite detail of proportion, order, and sculpture bestowed upon them. The ancient world is full of examples of this remarkable principle, and the last and most signal one is that in the temple at Balbec, by the Antonines, in which three stones measure, in the aggregate, upwards of 199 feet in length.

The Saviour, whose religion was soon to supersede all ancient laws, constantly illustrates his arguments by this practice: "the head stone, the chief of the corner, which the builders rejected," are his constant metaphors; and his prediction that of these great stones "there shall not be left one upon another," is literally verified in the subsequent history of Architecture.

Our remarks upon the uniform arrangement of plans of Greek and Roman temples, would be too long, and must be referred to the publications upon them specifically; but as brought together in this view it may be observed, that the temple at Ephesus, the size of which we learn alone from Pliny, exceeds all others in dimensions, and the constant limitation of length of the great temple to Jupiter especially (at Athens, Agrigentum, Selinus, Balbec, and Rome) to about 358 feet in length, might lead us to suspect the text of Pliny. Vitruvius gives us a few hints of the attachment of the ancients to numbers in his third book, with reference to the dimensions of temples. The investigation of this subject might be attended with curious results. The frequent dimension 358, by the addition of the stylobate, or by the local variation of the foot, may easily be supposed to refer to the number of days in the solar year. In the Temple or the Sun at Palmyra, the portico has 12 columns; these, added to the columns in the temple, make 52; the whole number of columns in the surrounding peribolus, is 364. Wren seems to have had reference to this idea in his height of St. Paul's.

The sections of Ægina, the Parthenon, and the temple at Pœstum, exhibit the arrangement of an interior divided into a nave and two ailes, by two rows of columns in double heights; those of Venus and Rome, and Balbec, exhibit the Roman form, namely, a vast vault—in these instances, upwards of 60 feet diameter in masonry. The occupation of the whole of these interiors by the idol, their employment as a vast niche to receive the god (in ivory and gold, at Olympia and Athens), had something of monstrous, but magnificent; and invested with the art of Phidias, we may understand how even the rough soldier, Paulus Æmilius, might be moved even to tears, as we are told, in the presence of the beauty and majesty of the godhead, as figured by that great master.

Arrived at that period (313 A.D.) in which the Christian religion was adopted by the state, the range of temples now exhibited displays a total reverse of the previous arrangement. The old ritual of external worship and of sacrifice was abrogated. It was now internal and of the heart; the portions were now inclosed; a vast area covered with a roof, of which the basilica was the best model, constituted the Christian temple. Upon this the cruciform was engrafted, "in hoc vince," bearing the universal symbol, in plan as well as in every other situation. The theory of the church of Constantine is handed down to us by Eusebius, bishop of Cæsarea; he describes the church of Tyre [which the Professor exhibited] and many others of his day, with the most interesting and instructive hints as to the signification and arrangement of sacred edifices, which may be very profitably consulted by the architect. The basilicas of St. Peter's and that of St. Paul's at Rome, in the form of the Latin cross, become the types of the Christian church throughout Western Europe, with very small variation (until the introduction of the dome, which then only modified it), down to the present day.

It was said that 1800 churches and religious structures were built during the reigns of Constantine and Justinian: those of the former were in the basilica form, which is liable to decay; those of the latter, to which the ritual and other important considerations gave a new form, resembled the Greek cross of equal lengths. The transept was covered with a large dome, and the ends of the cross with minor ones, forming a group highly favourable to architectural effect. This form, executed in Santa Sophia, became the wonder of the world, and the dome also, 120 feet in diameter, exceeded any executed since the Pantheon at Rome.

The Professor exhibited several Greek churches at Arta, Thessalonica, and other parts of Greece, measured by himself, as also the valuable researches on the Greek church architecture of the sixth and seventh centuries, by M. Couchaud, which contained many hints of great beauty and interest to the practical architect. The churches of Russia were all upon this plan. Procopius was the author, who might be consulted with reference to this era of the art.

The dome, which had become the distinguishing feature of the Eastern church, penetrated into Italy, under the exarchate at Ravenna, in the church Santa Vitali, 510 A.D; and again at Venice, in St. Mark's, built by a Greek architect (976—1071). Until the eleventh century, the dome formed no part of the western church, except in those instances; it was then that the Pisans, the richest and most commercial people of Italy, began their great church (1063), and adorned the transept with this new feature.

The rivalry of nations is the great fulcrum of many a noble effect, in arts as well as politics; and to this motive chiefly, we may attribute the bold scheme of Arnolpho de Lapo, in the church of Santa Maria, at Florence, founded in 1290; in which, doubtless, after the model of the Pantheon, he proposed to place a dome, of nearly equal magnitude, over the transept, but raised into the air in a way hitherto unattempted, except at Constantinople, where, however, the space was one-sixth smaller. But the inveterate and disastrous contests of these republics long deferred the execution, and it was not till one hundred and twenty years after, that Brunelleschi accomplished the work, as related in the very amusing and instructive account by Vasari.

It was just one hundred years after this successful work that Michael Angelo executed the dome at St Peter's, confessedly in imitation of it, as he told himself, in contemplating the model—

> Vò far la tua sorella.
> Piu grande già, ma son più bella.

In another one hundred and fifty years, we have the Domes of the Invalides, Val de Grace, at Paris, and St. Pauls, in London.

The family of Domes concludes with that of St. Genevieve (the Pantheon), and, like the successor of a noble but a worn-out race, exhibits all that meagreness and debility which precedes its extinction.

But the imitations of the types of the basilicas of St. Peter's and St. Paul's of Rome in the north and west of Europe,—*more Romano* to the eleventh century, from the eleventh to the sixteenth centuries *more Germanico*, by the societies of Freemasons,—have justly been the admiration of the world, for their unexampled hardihood and practical science, though the remarks on their principles of structure and of art, which the future lectures will have occasion to offer, will show that neither the geometrician nor the scientific architect need regret the impenetrable veil which conceals them. Any detailed discussion of the merits of the plans exhibited would lead beyond the bounds prescribed; but we must admit that, generally, the continental plans exceed our own in magnificence of design, especially in the double ailes and the western fronts. To what causes may be assigned the more modest design of our own churches, except to that characteristic prudence of our countrymen, which requires the full accomplishment of every enterprise undertaken, it may not be easy to determine; certain it is, that all the churches of this country are complete in their design and features, whereas those of the continent are very rarely so.

The words of our poet, though not always applicable to architects, unhappily, may be so to our pastors and masters.

> When we mean to build, we first survey the plot,
> Then draw the model: which if we find exceeds ability,
> What do we then, but draw anew the model in fewer offices.
>
> ——— Consult surveyors, know our own estate,
> How able such a work to undergo.
> Or else we build like those, who half thro' give o'er,
> And leave their part created cost
> A naked subject to the watery clouds,
> And waste for churlish Winter's tyranny.

With reference to the gradual verticality which the sections of this series of ancient and modern temples assumed, we might say, that the earliest were of the earth earthy, and the latter as sublime as the religion for which they were designed. Thus, the height of the Pantheon, at Rome, was equal to its diameter, or as 10 to 10; that of Venus, and Rome, was as 12½ to 10; that of the Baths of Caracalla, as 14 to 10; of St. Peter's, at Rome, as 17 to 10; of St. Paul's, London, 20 to 10, as also of Lincoln; and that of Cologne was as 34 to 10.

The last great temple of Christendom, was the Magdalene Church at Paris; it is 325 feet long by 136 feet wide and 120 feet high, and equalled the smaller temple at Balbec. It was the work of more than half a century. In England, great activity had been used in church-building during the last twenty-five years, but the warmest admirers of those zealous efforts could never pretend that any regulated architectural spirit has directed those works. No church of a monumental character had been attempted. The ascendancy of the high church party is, however, favourable to our art, and it is not unlikely, that under good direction, it may flourish in a few years. But there is much pedantry abroad, and an absence of all originality and intrinsic character in the taste of the day, which leans to the Roman Catholic form, the basilica, suited to a demonstrative form of worship, rather than the auditorium required by our ritual. Veneration for antiquity is to be respected and encouraged, but its transition to superstition is easy. The divines of 1680 have left us models, erected under the direction of Sir C. Wren, which have not been surpassed. Seven of the city churches were exhibited (measured by the Professor), which would be found as remarkable for their adaptation to our form of worship—offering the largest area, with the smallest obstruction to the sight and hearing,—as they were ingenious and admirable in taste and structure.

The favourite design of Sir C. Wren (laid down from the model now in St. Paul's,) was also exhibited. It was a precious legacy to posterity, which had never been surpassed in architectural beauty and arrangement, for the Anglo-Protestant Cathedral church, and would probably at some future time be executed.

But attachment to our national architecture may be indulged with great propriety by the adoption of the forms of the Lady Chapels, modified and suited to our ritual—as those of Wells, Ely, and others; or of the chapter-houses; and the Greek church. The basilica form requires length unsuited to our services, and the fragments or curtailed portions of that form, often practised with small success in our recent churches, seems to point at the greater advantage of the vertical arrangement, which the models, the Professor ventured to suggest, in the churches of Wren, and the examples quoted, would assure to us.

THE METROPOLITAN PAVING ACT.

An important case came before Mr. Hardwick at the Marlborough Police Office, on the 24th of December last, arising out of a dispute between the Equitable Gas Company and the Commissioners of Paving for the parish of St. James's, Westminster, as to whether the Equitable Gas Company had or had not the right of breaking up the street and afterwards lay down a service pipe "without the consent of the Paving Board." After hearing both parties, the Magistrate adjourned the case for consideration until Thursday, January 5th, when it was again heard for final adjudication.

Mr. Smith, solicitor, attended on behalf of the Paving Commissioners, and Mr. Clarkson, the barrister, for the Equitable Gas Company.

Mr. Hardwick read the following as his opinion:—This is a complaint by the Board of Pavements, in the Parish of St. James, against the Equitable Gas light Company, for breaking and taking up the pavement in their jurisdiction for the purpose of laying down a new pipe without the consent of the board. The answer of the Gas Company is, that it being a service pipe and not a main pipe, a notice only and not the consent of the board is required. The clauses which gave rise to the disputed point are in the 11th section of the 57th George III, cap. 29. Abridged they stand thus—"No water or gas light company shall break or take up the pavement in any street for the purpose of laying down any main or mains of pipes, unless notice in writing be given to the surveyor of pavements three days previous to such breaking up," &c. So far water and gas companies are placed upon the same footing; but in the next clause a further restriction is imposed on gas companies. By it no gas company can take or break up any pavement for the purpose of laying down any new mains or pipes without the consent in writing of the Board of Pavement. When my attention was first called to this clause, my impression was, that being, as it then seemed to me, in the disjunctive, the word "pipes" must be taken to include pipes of every description, and that the Board of Pavement was right in their view of the case. But on a more attentive perusal of this section, and especially of the following one, that impression has been much removed; and I am now inclined to think that the perplexity in this matter has arisen from an ambiguous use of terms, from using different expressions to signify one and the same thing; for example:—In the beginning of the 12th section, which directs of what materials mains should be, the language there used is worthy of observation. "That all new or complete mains, or pipes laid down in any street by any water or gas company, whether such new or complete main of pipes shall or shall not be substituted for, or added to, any other complete main or mains of pipes, shall be of iron alone." Here in these few lines we have three different expressions—mains, or pipes, main of pipes, and main or mains of pipes, all signifying one and the same thing—the main pipe. In the next clause separate and distinct mention is made of service-pipes, which may be either of iron or lead, or other durable material; from which I am induced to infer that, possibly, "or" is a typographical error for "of," or at any rate it is to be taken in a disjunctive sense, but, as it is frequently used, expressing an alternative of terms, a definition or explanation of the same thing in different words. Thus "main" being purely a technical word of the most comprehensive signification, the terms "pipes" and "mains of pipes" have been added and used as an alternative term to give it a clearer and more definite meaning for the purposes of this act, and therefore the expression "mains or pipes," in the clause under discussion, may not unfairly be read as synonymous with "mains of pipes," or pipes forming the main. If this should be the right view of the case, the complaint must be dismissed; as the pipe in question laid down is a service, not a main pipe, it requires notice only, not the consent of the board.

Mr. Smith argued that the 11th section of the act of Parliament related both to main and service pipes, whether they were for gas or water companies.

Mr. Hardwick said this question only applied to mains.

After a long discussion, Mr. Hardwick said he still adhered to the conclusion he had just read.

Mr. Smith observed, that unless there was a conviction before the magistrate, he had no power of appeal.

Mr. Hardwick said the proper court of tribunal was the Court of Queen's Bench.

Mr. Clarkson had waited very patiently while this discussion was going on. He was, however, very much surprised to hear that Mr. Smith had displayed so much ignorance with relation to the decision of those whom he (Mr. Clarkson) was proud to call his learned friends—viz., the present Attorney-General (Sir F. Pollock), or former Attorney-General (Lord Campbell), Mr. Adolphus, and another learned friend, all of whom had given opinions quite contrary to that which Mr. Smith now stood upon. He contended that the mains having been laid down at the house of any person applying, common law and common sense gave him the power, which the law of England gave every man, of having his own subsoil opened. He did not know whether it was, as the worthy magistrate had observed, a typographical mistake in the act of Parliament in substituting "or" for "of," or one of those tinkerings which he had so frequently observed in the machinery of acts of Parliament, but he must say the act was most defective. It was wind without sense; sometimes the word "mains" was used, and sometimes "pipes;" they were "*ejusdem generis.*" What a state of things it would be, if a collector was to come to a person who wished his gas to be laid on in the front of his house, and say he did not like his look; or, if another was to be asked to lay on the water, to say he did not admire his politics. Would such proceedings be tolerated? He was certain not. The tenant, the drains having been laid down, had a right to open the subsoil, and in his opinion he was fortified by the opinions of the eminent legal authorities he had mentioned. A similar case had been argued before Mr. Long by himself and his learned friend Mr. Bodkin, and the learned magistrate had, in that case, decided, notwithstanding all his learned friend's arguments, against him and the parochial commissioner.

A discussion was here raised between Messrs. Clarkson and Smith, as to whether or not notice had been given on the 11th of May by one of the inspectors of the gas company of his intention to open the street; Mr. Clarkson denied that such notice had ever been given.

Mr. Hardwick considered that, by the arguments which had been brought before him, and also by his own previously written opinion, the gas company were authorized to open the ground for service-pipes: the complaint was therefore dismissed.

REVIEWS.

An Encyclopædia of Architecture, Historical, Theoretical, and Practical. By Joseph Gwilt. Illustrated by more than 1000 engravings on wood. In one thick volume, 8vo., 1080 pp. London, 1842. Longman & Co.

SECOND NOTICE.

We may resume our notice of this work, by remarking that Mr. Gwilt indulges almost quite as much in criticism upon "critics," as upon buildings, and that as regards the former, he is apt to express himself with a degree of spleen against the whole race, that amounts to want of temper, and which certainly is not calculated to obtain for him their good word. Nevertheless, his present work has obtained unqualified, not to call it outrageous praise, from some of them; viz., those who write for newspapers, and in whose favour he is henceforth bound to make an exception. Most good-natured they certainly must be allowed to have shown themselves—that is, supposing they looked far enough into his book to meet with some of the ungracious reflections he has thrown out upon the fraternity of reviewers. Although not very thin-skinned ourselves, nor disposed to vindicate the pretensions of all our reviewing brethren, we must say, that Mr. Gwilt carries his hostility too far. He takes it for granted, that none of those who write upon architectural subjects in literary journals, are professional men, or if not belonging to the profession, can have qualified themselves by study, for the task they venture upon. Were the "catalogue of works on architecture," which he has given in his Encyclopædia, what it ought to be, it would contain many, and those not the least interesting or valuable of all, for which we are indebted to the studies of those whom Mr. G. would have us regard as little better than intruders and pretenders—persons who just know enough of the subject to assume a tone of authority, and mislead others. Since he has not thought proper to insert in that "Catalogue," such works as Hope's History of Architecture, Parker's Glossary, (now considered as a sort of authority,) and the publications of Rickman, Whewell, and Willis—not to mention others, which he has omitted; we must suppose that he estimates them not at all higher than the effusions of anonymous scribblers and reviewers, although they have obtained some character not only with the public, but with the profession also. What may be his standard of merit—where he has drawn the line between works that are, and those which are not worthy of being recommended to the student, we are unable to say, for he seems to be just as over-liberal and indulgent in some instances, as he is vigorous in others. Among the publications enumerated under the head of modern English architecture, we do not find the "Public Buildings of London," or Malton's "Picturesque Tour," which last, though not professedly architectural, as it contains only views, is an exceedingly interesting graphic work. Neither are Robert Adam's designs there mentioned, although those of James Lewis, a far less distinguished architect, are. Neither is Barry's "Traveller's Club House" inserted, notwithstanding that both the building itself is considered a tolerably favourable specimen of English architecture at the present day, and is more fully illustrated than almost any other individual edifice, exceping Holkham.

That these remarks are rather ungracious, and not likely to prove altogether palatable to Mr. Gwilt, we do not deny; but many of his own remarks are so exceedingly ungracious and illiberal, that he has no right to look for much forbearance on the part of others. Even while we are willing to give him credit for having the interests of architecture at heart, we think he has altogether mistaken the way in which they are to be promoted. Instead of expressing any satisfaction at finding that architecture now begins to excite far more attention than it used to do, he takes no pains to conceal his disapprobation of its being taken up as a mere pursuit, by those who do not apply to it professionally; which is almost tantamount to saying, that those who have a taste for the study, have no right to indulge in it, and to acquire that knowledge of the art, which is indispensably requisite, if they would really enjoy it, and become capable of judging of its productions:—which is certainly strange doctrine, and is so completely contrary to all views of sound policy, that, never, it is to be hoped, will it be adopted. Of that, however, we have little apprehension; were it ever so desirable, it is now too late to attempt to check what is, if not a rapidly advancing, a widely spreading taste. Far more reason is there to apprehend that the prejudices to which Mr. G. has given way, will raise up some prejudice against his own book: at all events, they are not calculated to obtain him good-will. And though on our own part we might have abstained from adverting to this characteristic of his Encyclopædia, we should have felt that by so doing, we were deserting the cause of architecture and its friends, and by our acquiescent silence, abandon many who have rendered important services to that cause, to the odium attempted to be thrown upon them by Mr. Gwilt.

To return to the volume itself: the more popular portion of it, namely, the historical, is by no means so full as it ought to be, and might have been, had space been obtained for that purpose, by omitting elsewhere a great deal of matter which there was not the least occasion to introduce at all. Of the architecture of many parts of the Continent, we meet with only hasty sketches, without any specimens of their buildings; and even the history of Italian architecture is cut short very abruptly, being brought down only to the beginning of the 17th century, as if the following and the present one had produced nothing of the least note. Yet some mention of Calderar and his works, if of no one else, might have been expected, from a professed admirer of the Palladian school, as Mr. G.

Of a work of this nature, it is hardly possible to convey a suitable idea by extracts or detached passages; nevertheless, we give those in which the characteristicts of the Florentine, Roman, and Venetian schools are spoken of, and respectively illustrated by an example.

"*Florentine School.*—Climate and the habits of a people are the principal agents in creating real style in architecture; but these are in a great measure controlled, or it is perhaps more correct to say modified, by the materials which a country supplies. Often, indeed, these latter restrict the architect, and influence the lightness or massiveness of the style he adopts. The quarries of Tuscany furnish very large blocks of stone, lying so close to the surface that they are without other difficulty than that of carriage obtained, and removed to the spots where they are wanted. This is probably a circumstance which will account for the solidity, monotony, and solemnity which are such commanding features in the Florentine school; and which, if we may judge from the colossal ruins still existing, similarly prevailed in the buildings of ancient Etruria. In later times another cause contributed to the continuation of the practice, and that was the necessity of affording places of defence for the upper ranks of society in a state where insurrection continually occurred. Thus the palaces of the Medici, of the Pitti, of the Strozzi, and of other families, served almost equally for fortresses as for palaces. The style seems to have interdicted the use of columns in the façade, and on this account the stupendous cornices that were used seem actually necessary for the purpose of imparting grandeur to the composition. In the best and most celebrated examples of their palaces, such as the Strozzi, Pandolfini, and others in Florence, and the Piccolomini palace at Sienna, the cornices are proportioned to the whole height of the building considered as an order, notwithstanding the horizontal subdivisions and small interposed cornices that are practised between the base and the crowning member. The courts of these palaces are usually surrounded by columns and arcades, and their interior is scarcely ever indicated by the external distribution. From among the extraordinary palaces with which Florence abounds, we place before the reader the exquisite façade of the Pandolfini palace, the design whereof (Fig. 1,) is attributed to the divine Raf-

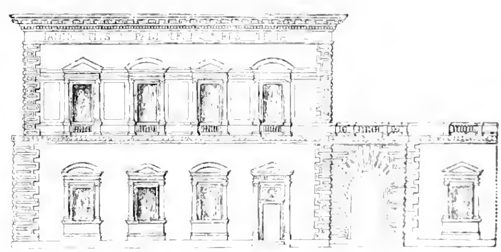

Fig. 1 PANDOLFINI PALACE.

faelle d'Urbino. In it almost all the requisites of street architecture are displayed. It is an example wherein the principles of that style are so admirably developed, as to induce us to recommend it, in conjunction with the façade of the Farnese palace hereafter given, to the elaborate study of the young architect.

"*Roman School.*—Though the city of Rome, during the period of the rise and progress of the Roman school of architecture, was not altogether free from insurrectionary troubles, its palatial style is far less massive than that of Florence. None of its buildings present the fortress-like appearance of those in the last-named city. Indeed, the Roman palaces, from their grace and lightness, indicate, on the part of the people, habits of a much more pacific nature, and an advancing state of the art, arising from a more intimate acquaintance with the models of antiquity which were on every side. The introductions of columns becomes a favourite and pleasing feature, and great care and study appear to have been constantly bestowed on the façades of their buildings; so much so, indeed, in many, that they are but masks to indifferent interiors. In them the entrance becomes a principal object; and though in a great number of cases the abuses which enter into its composition are manifold, yet the general effect is usually successful. The courts in these palaces are most frequently surrounded with arcades, whence a staircase of considerable dimensions leads to the sala or principal room of the palace. The general character is that of grandeur, but devoid altogether of the severity which so strongly marks the Florentine school. The noblest example of a palace in the world is that of the Farnese family at Rome.

"The palaces of Rome are among the finest architectural works in Europe; and of those in Rome, as we have before observed, none equals the Farnese, whose façade is given in Fig. 3, 169. "Ce vaste palais Farnese, qui à tout prendre, pour la grandeur de la masse, la regularité de son ensemble, et l'excellence de son architecture, a tenu jusqu'ici, dans l'opinion des artistes, le premier rang entre tous les palais qu'on renomme," is the general description of it by De Quincy, upon whom we have drawn largely, and must continue to do so. This edifice, by San Gallo, forms a quadrangle of 256 feet by 185 feet. It is constructed of brick, with the exception of the dressings of the doors and windows, the quoins of the fronts, and the entablature and loggia in the Strada Giulia, which are of travertine stone. Of the same stone, beautifully wrought, is the interior of the court. The building consists of three stories, including that on the ground, which, in the elevations or façades, are separated by impost cornices. The only break in its symmetry and simplicity occurs in the loggia, placed in the centre of the first story, which connects the windows on each side of it by four columns. On the ground story the windows are decorated with square-headed dressings of extremely simple design; in the next story they are flanked by columns, whose entablatures are crowned alternately with triangular and circular pediments; and in the third story are circular-headed windows, crowned throughout with triangular pediments. The taste in which these last is composed, is not so good as the rest, though they were probably the work of Michael Angelo, of whose cornice to the edifice Vasari observes:—" E stupendissimo il corniccione maggiore del medesimo palazzo nella facciata dinanzi, non si potendo alcuna cosa ne più bella ne più magnificà desiderare." The façade towards the Strada Giulia is different from the other fronts in the centre only, wherein there are three stories of arcades to the loggia, each of whose piers are decorated with columns of the Doric, Ionic, and Corinthian orders in the respective stories as they rise, and these in form and dimensions correspond with the three ranks of arcades towards the court. It appears probable that this central arrangement was not in the original design of San Gallo, but introduced when the third story was completed. Magnificent as, from its simplicity and symmetry, is the exterior of this palace, which, as De Quincy observes:—" est un édifice toujours digne d'être le sejour d'un prince," yet does it not exceed the beauty of the interior. The quadrangle of the court is 88 feet square between the columns of the arcades, and is composed with three stories, in which the central arrangement above mentioned towards the Villa Giulia is repeated on the two lower stories, over the upper whereof is a solid wall pierced in the windows. The piers of the lower arcade are ornamented with Doric columns, whose entablature is charged with triglyphs in its frieze, and its metopæ are sculptured with various symbols. The impost of the piers are very finely profiled, so as to form the entablatures, when continued, over the columns of the entrance vestibule. In the Ionic arcade, over this, the frieze of the order is decorated with a series of festoons. The distribution of the different apartments and passage is well contrived. All about the building is on a scale of great grandeur. Though long unoccupied, and a large portion of its internal ornaments has disappeared, it still commands our admiration in the Carracci Gallery, which has continued to serve as a model for all subsequent works of the kind. The architecture of the Farnese palace, more especially as respects the arcades of its court, is the most perfect adaptation of ancient arrangement to more modern habits that has ever been designed. We here allude, more particularly, to the arcades, upon whose piers orders of columns are introduced. This species of composition, heavier, doubtless, less elegant, yet more solid than simple colonnades, is, on the last account, preferable to them, where several stories rise above one another. The idea was, certainly, conceived from the practice in the ancient theatres and amphitheatres; and in its application at the Farnese palace rivals in beauty all that antiquity makes us in its remains acquainted with. San Gallo, its architect, died in 1546."

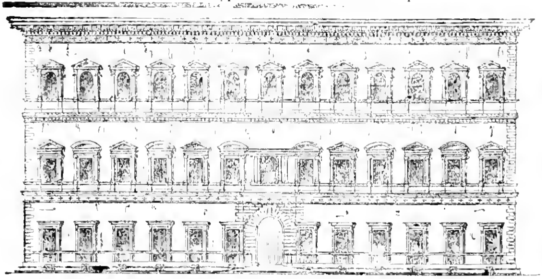

Fig. 1. FARNESE PALACE.

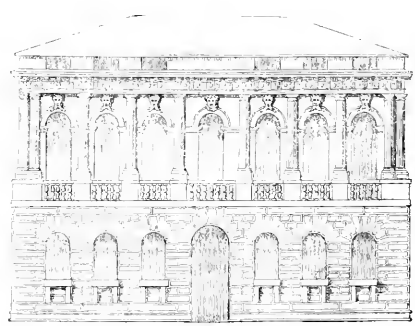

Fig. 2. POMPEI PALACE, VERONA.

The Venetian school is spoken of at much greater length than the others, and is, in our opinion, not a little over rated; for when we come to examine some of its most noted productions, we find them to be made up of insignificant parts, and petty orders treated in a formal, dry, and meagre manner, without any of that richness, or of that artist-like freedom, which would reconcile us to the orders being employed merely in half-columns and pilasters, as decorated to one or more stories of a building.

"*The Venetian School* is characterised by its lightness and elegance; by the convenient distribution it displays; and by the abundant, perhaps exuberant, use of columns, pilasters, and arcades, which enter into its composition. Like its sister school of painting, its address is more to the senses than is the case with those we have just quitted. We have already given an account of the church of St. Mark, in the 12th century; from which period, as the republic rose into importance by its arms and commerce, its arts were destined to an equally brilliant career. The possession in its provinces of some fine monuments of antiquity, as well as its early acquaintance with Greece, would, of course, work beneficially for the advancement of its architecture. That species of luxury, the natural result of a desire on the part of individuals to perpetuate their names through the medium of their habitations, though not productive of works on a grand or monumental scale, leads, in a democracy (as were the states of Venice), to a very general display of moderately splendid and elegant palaces. Hence the extraordinary number of specimens of the building art supplied by the Venetian school.

"San Micheli, who was born in 1484, may, with propriety, be called its founder. Having visited Rome at the early age of 16, for the purpose of studying its ancient monuments of art, and having in that city found much employment, he, after many years of absence, returned to his native country. The mode in which he combined pure and beautiful architecture with the requisites called for in fortifications may be seen displayed to great advantage at Verona, in which city the *Porta del Pallia* is an instance of his wonderful ingenuity and taste. But his most admired works are his palaces at Verona; though, perhaps, that of the Grimani family at Venice is his most magnificent production. The general style of composition, very different from that of the palaces of Florence and Rome, is marked by the use of a basement of rustic work, wherefrom an order rises, often with arched windows, in which he greatly delighted, and these were connected with the order after the manner of an arcade, the whole being crowned with the proper entablature. As an example, we give in Fig. 3, the façade of the Pompei palace at Verona. The genius of San Micheli was of the very highest order; his works are as conspicuous for excellent construction as they are for convenience, unity, harmony, and simplicity, which threw into shade the minor abuses occasionally found in them. If he had no other testimony, it would be sufficient to say, that for his talents he was held to be in great esteem by Michael Angelo; and our advice to the student would be to study his works with diligence. San Micheli devoted himself with great ardour to the practice of military architecture; and though the invention was not for a long time afterwards assigned to him, he was the author of the system used by Vauban and his school, who, for a long period, deprived him of the credit of it. Before him all the ramparts of a fortification were round or square. He introduced a new method, inventing the triangular and pentangular bastion, with plain fossés, flanks and square bases, which doubled the support; he moreover not only flanked the curtain, but all the fossé to the next bastion, the covered way, and glacis. The mystery of this art consisted in defending every part of the inclosure by the flank of a bastion; hence, making it round and square, the front of it, that is, the space which remains in the triangle, which was before undefended, was by San Micheli provided against.

In this example of San Micheli's style, the Palazzo Pompei at Verona, the basement is the best part of the composition, for the order is too small in proportion to the rest, and the openings on the principal floor as much too large, at least as windows, for the piers between them must be most inconveniently narrow within. It is rather singular, that while he was upon the subject of Italian architecture, Mr. Gwilt should not have alluded to the recent introduction of the *palazzo* style, in this country. As an example of it, he gives the façade of the Palazzo Pandolfini at Florence, strongly recommending that and the Palazzo Farnese, to the "elaborate study of the young architect," but without informing him, that by going into Pall Mall, he would perceive what use had been made both of the one and the other, by Mr. Barry, in the two adjoining club houses—the Travellers and the Reform. Though neither copies nor even imitations—in the ordinary meaning of the term, they are evidently borrowed from those prototypes, which in point of mere taste, are there improved upon and refined. The Reform Club House has been spoken of, by some, as being a direct copy of the Farnese; with what justice or judgment, may be seen from the above representation of the latter, which though too small to do more than afford an idea of the general composition, shows the manner in which the entrance and window on each side of it are squeezed together, produces anything but an agreeable effect; while the centre window above, exceptionable in character at the best, is, so introduced as to constitute a striking blemish in the whole design.

We must now take leave of Mr. Gwilt's work, which we should have been happy to have been able to speak of in less qualified terms of approbation. It contains a great deal of valuable, but not so much fresh matter as it might have done; but it also contains many opinions which we should be the last to support, and which are not likely to gain ground with the public, at the present day. We cannot, however, conclude, without expressing our high approbation of the spirited manner with which the publishers have got up the work, both in the typography and illustrations; the latter are beautifully executed as wood, or may be seen by the above specimens, which we have been permitted to select from the work.

Ensamples of Railway making; which, although not of English practice, are submitted, with Practical Illustrations to the Civil Engineer, and the British and Irish public. London: Architectural Library, 59, High Holborn.

The great disparity between the cost of railways in this country and that of similar works in America, is worthy at the present time of giving rise to some important considerations. Whilst on this side of the Atlantic, our main lines of railway have been constructed of materials extremely durable, in a manner remarkable for strength and solidity, and according to a standard of excellence with respect to gradients, which far surpasses any thing that has been attempted under like circumstances in other countries, the policy of absorbing such vast sums of money as have been required to effect all this is at least open to controversy. Hitherto every thing has been done in accordance with our national character, and never has that spirit of energy and industry which marks the Briton under every varying circumstance of time and distance, been more proudly exhibited than in the bold and ardent expedition with which the surface of his country was chequered by a net work of great commercial highways, constructed in almost every respect on principles the very antipodes of those which have guided other nations in their imitation of the same spirit. Seizing at once upon the experimental fact, that the friction of iron wheels upon iron roads is incomparably smaller than upon roads of stone, and connecting this with the no less certain truth, that resistance to motion is made up of friction and gravity, the English engineer conceived the grand idea of almost annihilating gravity by reducing the track of the railway to nearly a perfect level. It was demonstrable that the same absolute power which could impel a given weight on a common road at 10 miles an hour, would, on a level railway, impel five times that weight at treble the velocity, and it was further unquestionable that an inclination greater than 1 in 221 would at least double the power required to effect this, and thus diminish the superiority of the railway by one half. If a horizontal railway be compared with a horizontal common road, the superiority of the former over the latter is as 15 to 1; but if a railway inclining 1 in 30 be compared with a common road also inclining 1 in 30, its superiority in this case is only as 1½ to 1. Following out the principle of which these are illustrations, it is no less obvious now than it was in the origin of railways, that the more nearly the planes of a railway approach to a level, the more superiority will they present over the common road. It was this principle which demanded in the name alike of science and of commerce, that in the track of the railway every mountain should be brought low, and every valley should be filled up; it was this which caused the transport of vast masses of earth from the higher to the lower parts of the country, which forced the deep excavation, reared the lofty embankment, bored the yawning tunnel, and dealt with all the most solid materials of earth, as if they had been the playthings of a baby's doll-house, instead of fabrics which require to be encountered by the sinews of hosts and the wealth of nations.

For, acting on principles which appeared to be sanctioned by every maxim of wisdom and experience, who can blame, with any show of reason, the engineers of this country, to whom the world is so much indebted, no less in the early origin, than during the steady progress of railway engineering. Fifteen years ago, when railway science was in its infancy, no voice was raised in opposition to the principle of almost horizontal gradients, and the necessity for those gigantic works which this principle demanded was as heartily acquiesced in by directors, by shareholders, and by the whole public, as by the engineers themselves. Nay, had it been otherwise—had the engineers stood alone in support of their principle—had the public voice been against them—and had the public press branded their projects as extravagant and wasteful, we are amongst the number of those who contend that they would still have done right to maintain their principle, and we should have applauded and admired them the more for carrying, in the first instance, a superior degree of excellence into those works which were destined to furnish an example to the whole civilized world. We confidently appeal to any competent judge, who, thoroughly understanding the mechanical and political distinctions between the railway and the common road, shall fairly and dispassionately review the circumstances of this country, whether we should have done well or wisely to adopt a less horizontal succession of planes for those main lines which are probably destined to endure for ages, as the great arteries through which commerce will ramify into a thousand inferior channels all over the face of the country. While we thus regard with great satisfaction the superior character with respect to gradients which has been adopted for all the great railways of this country, there is yet another element in their construction, which, while it influences in no degree whatever the facilities for locomotion, yet contrasts remarkably in point of expense with corresponding works on the American lines. We shall readily be understood here as referring to those costly bridges and viaducts of iron, brick and stone, which have so enormously swelled the estimates for executing our principal railways. To decide upon the kind of gradients to be adopted for a given line of railway—a decision which regulates, more than any thing else, the cost of its construction—required, in the first instance, only a knowledge of simple principles, and in the absence of that experience which later years have supplied with respect to the comparative expense of working lines with steep and with level gradients, our engineers acted in a spirit of perfectly sound wisdom, when they laid the greatest practicable tax upon capital for the purpose of enabling the nation to realize, in its full extent, the superior advantages of railway transit. But in deciding on the style and character of the attendant works, which are entirely independent of the surface of the railway, the question assumes a purely commercial aspect, and may be thus stated: Suppose a line of railway with the most complete and substantial works of masonry, to have cost, say, one million of money, and suppose the same line could have been constructed with a more perishable class of works, as for instance, bridges and viaducts of timber, at an expense of half this sum, which kind of work is it most judicious to adopt, having regard to the circumstance, that after the lapse of a certain number of years the constructions of timber will require to be renewed, whilst those of masonry would require only very trifling repairs. Suppose in the former case, where the railway had cost a million sterling, the interest derived from the expended capital would amount to 5 per cent per annum. It is clear that in the latter case, where the line only cost half a million, the interest derivable on the capital would be 10 per cent. Now supposing 5 per cent of this to be set aside as a reserved fund, would the works of timber last so long a time as not to require restoration, until the reserved fund had sufficiently accumulated to effect this restoration? This is the grand point which should decide between the adoption of timber, or a more expensive and durable material for the architectural works of railways. We are not here to be understood, for one moment, as contending that any such proportion, as that which has been assumed, exists between the cost of a railway with stone bridges and viaducts and one in which their works are of wood. What we have said, however, will be sufficient to indicate the general principle of the comparison, and the utmost concession we are prepared at present to make to the champions of cheap and therefore temporary railways, is this, that the comparative cost and the comparative durability of the two classes of works are, in all cases, worthy of being considered by the engineer in connexion with the estimated amount of revenue derivable from any given line.

We are aware that, in all this, we are stating nothing new to the engineer; nothing but what has already occurred to most of the leading members in the profession, and nothing but what will be extensively practised, in laying out the numerous branch railways, which the convenience of the country still requires. Our object in making these observations, will be amply fulfilled, if they succeed, in disabusing some part of the public mind, of the notion, that the costly stations and bridges and viaducts are all that distinguish our railways from those of Europe and of America. It should be remembered, that the much larger capital expended on our works has effected a system of levels, which enables us to command far higher speeds, and to realize, in every way, greater advantages from the railway, as compared with the common road. In every case where it is desired to take a comprehensive view of railways, as a political question, it is essential to distinguish between that part of the cost which is due to the superior character of the buildings connected with the railway, and that which is incurred in conformity with principles immediately connected with the facilities for working locomotive power. On the former of these points, we grant, that a statesman, a merchant, or a financier of any kind, may form a competent judgment, with proper data before him. On the latter, the only qualified judge is the engineer, because a decision must in most cases be made with reference to the future, and particularly with reference to the future auspices of engineering and mechanical skill. Thus, in the origin of railways, the engineer alone was qualified to chalk out a system of gradients which should correspond with the known properties of the locomotive engine, and of iron as a material for the wheels of carriages to roll upon—so in like manner Mr. Brunel, or those of like qualifications, are alone entitled to consideration in deciding such a question as that of the gauge to be adopted for the Great Western Railway, because the accuracy of the decision depended upon the truth or error of certain prognostications in physical science, which a mere financier, however able, is not competent to entertain. The engineer, in fact, must regulate his operations, both by past experience and by anticipations of the future; to what extent these latter are or should be based upon, the former depends on many circumstances, but to some important extent, all will admit, that the past should influence our future projects of every kind. It would, therefore, be highly desirable at the present time, that accurate and comprehensive returns should be framed of the actual working cost of locomotive power on all railways of every different rate of inclination, in order that a correct judgment may be formed upon the influence which gradients really exert in affecting the working expenses of railways. Thus would information of great value be placed at the engineer's command; but until sufficient data have been obtained to clear this subject of the obscurity which now rests upon it, we certainly must protest against the blind and wholesale jumbling which has been perpetrated by some who profess to be authorities on the subject of railway estimates. We insist, most strongly, upon the necessity for separating the cost of attendant works from those which have been rendered essential purely by the character of the gradients adopted; and we warn all those, who, without any engineering knowledge to guide them, shall be rash enough to commit themselves to paper, on subjects of this nature, that the less they have to do with the engineering part of the subject the better. The attendant works, as we have said, involve more or less of commercial considerations, and these should therefore be free for discussion; and anything possessing novelty and merit, which can be placed before the engineer in the way of designs, applicable to such attendant works, will no doubt be received by the profession at large with interest and gratification.

The spirited publisher of the work before us, is already too well known, and too highly valued by the profession to require anything from us in the way of general praise. If any such testimony were wanting, it will always be gratifying to acknowledge the many valuable contributions to engineering science, which Mr. Weale has originated, and which he has been something more than a secondary means of giving to the world. In the production entitled Railway Ensamples, however, Mr. Weale appears before us in a new character. He has here assumed the province of authorship, and in this capacity places himself before the bar of public opinion, subject to that judgment, whether of condemnation or approval, which that severe tribunal hesitates not to pronounce, on all who thus prominently court her notice. In some respects, we feel bound to congratulate Mr. Weale upon the character he has here assumed—we hail with pleasure, on a first view, the modest and simple announcement of the titlepage, and assuming the value of his examples, as specimens of design, we are glad to perceive that an individual has had the spirit and sagacity to present to the notice of the English engineer a connected series of works from a foreign railway. On looking further into their examples, we find them to be drawn from the Utica and Syracuse Railway, an American line about 53 miles in length. Whether these examples be worthy or not of presentation, in such a form, to the engineers of this country, is not now the question: supposing they are so, the profession is undoubtedly much indebted to the individual who has thus incurred the pains and expense of bringing them before their notice. Mr. Weale's appearance in the character of an author, however, is not limited to the dry and brief notices which are required to illustrate a set of railway plates, but embraces a somewhat extensive catalogue of subjects connected with railway engineering which have been condensed into 40 pages of preliminary observations. These observations are accompanied by several maps, and by plates of an American locomotive engine, and an American earth excavator. Although we cannot agree with the writer in many of these preliminary observations, we have at the same time great pleasure in stating, that the reader will find amongst them much that is interesting and amusing. We may mention particularly the description of the American locomotives, and that of the Satellite engine on the London and Brighton Railway. We are not able to say much in praise of the excavating machine; it appears to be a very clumsy affair, encumbered by a mass of machinery out of all proportion to the effect required. Its economy is extremely doubtful except when put in competition with very high prices for labour, in which case it might possibly be more economical than manual labour for excavating earth. The machine is said to be capable of excavating 1500 cubic yards in 12 hours, at a cost for fuel of 12*s.* per diem. To this statement, Mr. Weale adds, that "earthwork in England has generally been taken at 10*d.* to 1*s.* per yard." He forgets, however, that this price includes the carriage or haulage of the earth, and that the price of getting and filling the stuff, which is all that the American machine performs, is commonly not more than from 2*d.* to 5*d.* per yard. It is, therefore, some mean between these two prices which should be taken for comparison with the machine; but at present, we are not able to make this comparison, having no information as to her cost and working expenses.

A second division of the preliminary observations is principally directed to a comparison between the cost of the American railways and those of this country. The principal facts on which Mr. Weale argues, are these, that the aggregate cost of the American railways was estimated in 1839, at £4000 per mile, including all buildings and apparatus; and secondly, that actual works are not executed cheaper in America than in this country, as the greater expense of timber here is counterbalanced by the greater expense of labour there. He therefore, concludes that the greatly increased cost of the English railways has been caused by the more expensive nature of the works, that is by the difference of the two systems of construction. This is undoubtedly true to a certain extent, and here the comparison might cease, with this observation, that we have obtained far superior railways, by expending more money in their construction than the Americans. In case, however, any erroneous notions may be formed as to the comparative eligibility of the two systems, which are here contrasted, it may be sufficient to suggest, that no *fair* comparison can be made without full particulars, not only of the works executed on each, but also of the gradients and curves with which the lines were respectively constructed. It will be found that gradients of 25 to 30 ft. per mile are considered highly favourable in America, whereas, those of greater steepness than 15 or 16 feet per mile, have been held in this country to be highly objectionable. Again, as to curves, the American lines abound with sharp bends, which are quite inadmissible in those of Great Britain. A large proportion of the American lines are graded only for single lines of way; and in many of those which are graded for double lines, only a single track has been laid down. The cost per mile, as stated above, furnishes a very unfair comparison, in every respect, with the English lines, where the gradients and curves are entirely of a different order, the works are far more substantial, are mostly constructed for a double line of way, and where the cost of land has necessarily been excessive; whereas, in America the land in many cases has cost almost nothing. Another important point of comparison is the annual expense of working the railways in the two countries. M. De Gerstner estimated, in 1839, that the annual expense of working the American lines was 63·61 per cent. of the gross income, and that the interest on the whole capital invested in railroads in the United States does not exceed 5½ per cent. per annum. Now this annual expense is far greater than that of working the English railways—as, for instance, the Grand Junction costs 55·53 of the income, the Great Western 51·87 per cent.; and taking the average of all the railways, it would be found considerably below the American lines. In the case of the English lines, this amount will be still further reduced when their heavy earth works become perfectly settled, and no longer subject to those slips which, up to this time, have occasioned such heavy expenses. We find that the average dividend of 32 railways reported in the *Railway Times* amounts to 4*l.* 10*s.* per cent. per annum, which, although less in absolute amount than that produced by the American lines, is in reality far greater when the prospective circumstances are considered. Thus, for instance, supposing the slight timber bridges and viaducts of the American lines will last 20 years, which is a favourable supposition, where is the capital to come from in order to effect their restoration at the end of that time. Undoubtedly it can scarcely be reserved out of the present dividends of 5½ per cent., for nearly the whole amount will be required to provide the large capital for restoring their perishable works. On the other hand, the English lines, firmly and substantially constructed, are paying a steady dividend of 4½ per cent. on the average and no reserved fund is required, as the works are calculated to endure for many centuries. The conclusion to be drawn from all this is highly unfavourable to the American system, and at the same time encouraging to those who have embarked their capital in our own lines. While the railways of the United States must inevitably, in a very few years, present a condition of premature decay, with a hopeless prospect of restitution, those of this country will, in all probability, afford a more favourable investment for capital than at the present day. We have no wish to dispute much that is really valuable and ingenious in the railways of the United States, but we must contend against these lines being held up as a model for the great trunk lines of this country. Mr. Weale points out several lines in which he considers the American system would be applicable, and particularly advocates its adoption in Ireland. With certain restrictions, and under certain circumstances connected with the expected revenue, and the capital available to the undertakings, the American system of cheap *temporary* constructions and inferior gradients may be advisable for some lines in Ireland, but we should extremely regret to see the main lines in that country laid out on such a principle.

The most valuable part of Mr. Weale's book, because the most practical, and that which contains the most information is that which relates to the bridges actually constructed for the American railways.

The Utica and Syracuse Railroad, which has been selected as affording so favourable a specimen of cheap engineering in the United States, forms part of the great line of communication across the states of Massachusets and New York. This great line, which has been executed by several different companies, is upwards of 530 miles in length. It commences at Boston, in Massachusets, and passing through or near the towns of Worcester, West Stockbridge, Albany, Schenectady, Utica, Rome, Syracuse, Auburn, Waterloo, and Worcester, sweeps along the southern shore of Lake Ontario, for the last 200 miles of its course, from the Atlantic Ocean, and terminates at Buffalo, the north-eastern extremity of Lake Erie. The part of this great line which lies between Utica and Syracuse, is 53 miles in length, and throughout its course it follows the line of the Erie Canal. We have no information as to the gradients on this line, but judge that that they must be extremely favourable, as the Erie Canal was on a perfectly dead level, without any canal lock whatever between Utica and Syracuse, and for several miles east of the former place.

After an attentive examination of the plates referring to these bridges, we feel bound to pronounce that, as specimens of carpentry, they possess by no means superior merit. In place of that admirable system of timbers abutting against each other, which gives so much stiffness to some of the best specimens of English carpentry, the light planks of the American bridges are held together by an innumerable quantity of bolts, and the proper strength of the timber is not applied to the fullest advantage. The white pine, which is used so extensively in the American bridges is a timber very little known in this country. It is a white wood with a short grain, possessing little strength of fibre, and abounding in small black knots; it is used a good deal in Edinburgh and other parts of Scotland for the interior of houses, but is never applied to external work.

In addition to the plates of the bridges, and of the viaduct over a considerable valley and creek on this railway, there are several plates, showing the system of piling and laying the permanent way on a part of the line about 19 miles in length which was laid upon piles, the remaining length being graded, as it is called in America, that is formed by cuttings and embankments, as usual in this country.

There are also several plates showing culverts, but these possess little interest for the English reader; nor could the engineer derive any advantage from a comparison of this part of the American railway system with his own. The last portion of the work contains an interesting account (historical and statistical) of the Belgian railways by Mr. Edward Dobson, but we believe this part of the work is only a translation.

These ensamples of railway making, affording the best account which has yet been published in this country of the railroad works of the United States, will certainly find a place in the library of every engineer. Although we cannot consent to the wholesale adoption of the American system which Mr. Weale appears to advocate, there are yet many cases, both here and on the continent, in which these examples will prove very useful in railway engineering. We must not omit to mention, in conclusion, that the plates, as in all Mr. Weale's works, are admirably executed, and the details are so well shown that the most ordinary capacity may readily comprehend every part of the construction.

The Principles and Practice of Land, Engineering, Trigonometrical Subterraneous, and Marine Surveying. By Charles Bourns, C. E. London: John Ollivier.

We need scarcely say that on all occasions we feel much greater pleasure in speaking well of any book which comes under our notice than when we are obliged to pronounce an opinion of almost unqualified censure. In the present instance, however, an impartial reviewer has only the latter alternative; and we could wish sincerely for the credit of the profession both at home and abroad, that the production of works with such feeble claims upon public favour were much less rare than it is. We are told in the preface of Mr. Bourns' book, that the aim with which it is written has been "the formation of a book of reference." Had this really been the case, had the volume been merely a work of reference, and had it been so styled on its title-page, we should have known what to expect, and should never have been deceived into supposing that we were opening a book containing the principles and practice of every kind of surveying. But we are told in a few lines further on in the preface, "that the volume is intended to constitute a consistent whole; so that to understand an advanced part, a person must be conversant with what goes before." How then can it be a work of reference in the common acceptation of this term, since by the author's own showing, it requires a regular study to be made of what goes before, in order to understand any advanced part. Surely this destroys its value as a work of reference. Indiscriminate censure is seldom just, and in the present case we are far from saying that the book before us is absolutely worthless, and that there is nothing in it which might be instructive to the professional man. At the same time we feel bound to enter a strong protest against that too prevalent system of book-making of which this work is a remarkable specimen. It contains an immense mass of antiquated information injudiciously selected and badly arranged. The few grains of original matter which are scattered through its pages relate to minute points of professional practice, often magnified into undue importance, and introduced to the exclusion of more valuable things for no reason that we can discover, except that they happen to have formed part of the author's own practice, or to have been introduced by some of his friends. We make no pretence of having waded through the whole contents of this book, which is an octavo volume of 356 pages; but having looked into several of those parts of it which are not purely elementary, the general impression is by no means such as to encourage a further search. In every point of view the work is far inferior to those of Mr. Bruff, and to Mr. Williams' Geodesy, books which have been reviewed in former numbers of the *Journal*.

Blunt's Civil Engineer and Practical Mechanist. Division C. Portion the Second. London: Ackerman and Co.

This portion is principally devoted to the delineation and description of machinery by the Messrs. Rennie. The first plate is of the gun-boring and turning mill, with the lathe apparatus—machinery used in gun and engine manufacture. Another plate is of Messrs. Rennie's great boring lathe; it is used in the boring of cylinders, condensers, air pumps, and bored vessels of engines and mills, and in turning pistons, rods, shafts and journals. Three plates are of their marine dredging and excavating machine, part of which was in the first portion. The last plate is devoted to Sir Isambard Brunel's shield for the Thames Tunnel. We must observe, however that although we have used the term plate to express the several sheets, many parts of the works are separately described on each sheet, and form valuable drawings for reference.

Turning and Mechanical Manipulation, intended as a Work of General Reference and Practical Instruction, on the Lathe and the various Mechanical Pursuits followed by Amateurs. By Charles Holtzapffel, A. Inst. C. E.

Mr. Holtzapffel looking at the dearth of works on the arts professed by the mechanical engineer, has felt himself called upon to bring before the public the results of his experience on a subject of so much interest and value. It is fortunate, perhaps, for the mechanical engineer, that turning and many other of his pursuits have for a long period formed a favourite occupation with many wealthy individuals, as thereby an amount of patronage has been conferred on the tool maker, such as could have been obtained by no other means, and which has powerfully conduced to the improvement of the tools used in this important department, while many experiments have been made at private expense, which could scarcely have been executed by persons engaged in business. With a class of wealthy amateurs to whom to look for supporters, Mr. Holtzapffel could scarcely have rendered a more acceptable service than the production of a work, which, both to the practical man and the amateur, must be of high utility. Mr. Holtzapffel, in the resources of his large establishment, and availing himself of the experience of his predecessors in the firm, possesses many advantages for the task he has undertaken, and seems to devote himself to it *con amore*. The treatment of it he proposes to enter into at some length, and we can scarcely blame him for this, as the public will profit by the extent of labour devoted to the subject.

The volume now before us is one of five, and is devoted to the consideration of the various materials used. The second will discuss the principles of construction and application of cutting tools; the third will treat of hand turning; the fourth of complex or ornamental turning, and the fifth of the principles and practice of amateur mechanical engineering.

The description of the materials is distributed into three classes; the vegetable, the animal, and the mineral kingdoms. The description of the various kinds of woods, not only developes new facts as to their technical peculiarities, but illustrates their botanical characteristics, a portion of the work to which Professor Royle has contributed his valuable assistance. The materials from the animal kingdom, which are treated with no less ability, include shells and mother of pearl, bones, horn, tortoiseshell, whalebone and ivory. The materials from the mineral kingdom, embrace clay, amber, jet, cannel coal, the ornamental and precious stones, the metals and their alloys. To state, however, that the work is limited to a simple description of these materials, would convey an inadequate idea of its value, as it abounds with practical descriptions of many important or interesting processes. Thus we have observations on seasoning, softening, bending, and colouring wood; the manufacture of iron; forging, hardening and tempering of iron and steel; the melting and mixing of metals; and the properties of alloys; casting and founding; wire drawing and soldering. To the description of tempering alone twenty-five pages are devoted, and the subject is treated with a minuteness and ability, which leave nothing to be desired.

The Atmospheric Railway. Observations on the Report of Sir F. Smith and Professor Barlow. By Thomas F. Bergin, M.R.I.A. Dublin: Hodges and Smith, 1843.

Considerable controversy has existed on this subject, and a long correspondence has taken place between Mr. Bergin and Professor Barlow; with respect to it, we, however, are more inclined to look forward to the result of the great trial now in progress at Dublin, than to depend upon any mathematical formula, upon the bases of which no party seems to be agreed. The experiment will soon be satisfactorily settled one way or other, and the merits or demerits of the atmospheric system, will be shown in all their extent. Mr. Bergin has devoted considerable ability to the discussion of the subject, and the many who saw reason to distrust Professor Barlow's deductions, cannot do better than consult this pamphlet.

A Series of Diagrams, Illustrative of the Principles of Mechanical Philosophy. Drawn on Stone, by Henry Chapman, and Printed in Colours, by C. F. Cheffins. London: Chapman and Hall.

The fourth and fifth parts illustrate the pulley, inclined plane and wedge. The plan, which is that of giving practical and useful applications of the simple powers is well carried out, and thus both theory and practice are at once brought to bear on the instruction of the student; while it is not only a good work for the machinist, but an excellent drawing book. The work contains so many illustration valuable machines, that we feel ourselves still more strongly called upon to urge the necessity of some letter-press explanations accompanying the plates, treating on the theory of the powers and their several applications.

The Literary and Scientific Pocket Book. By J. W. Gutch. London: Lumley.

This contains much valuable matter of reference, and as such, we have much pleasure in recommending it to our readers.

ON THE STRENGTH OF BEAMS.

Sir—The problem proposed for solution by your correspondent "Concrete," at page 27 of the last month's *Journal*, is certainly one of great interest and importance; as he states, I believe, it has not been investigated in any of the standard works on the strength of materials. Like all questions connected with the strains of beams, it is one which, whether considered theoretically or practically, is of the most complicated nature and of great difficulty; particularly if investigated with mathematical accuracy. There are so many data to such questions, varying in each particular instance—so many circumstances which modify the general result—such as the deflection of the beam, and consequent variation of the length of leverage, the position of the neutral line, &c., that since the time of gables to the present day, they have always been considered as questions of the greatest difficulty; and yet there is no subject connected with theoretical mechanics more interesting to the engineer; none more useful, especially in the present age, when timber and iron are so extensively used in the most stupendous structures, the economy and durability of which depend so much upon the proper application of mechanical principles. I am sorry to say, however, that even now, there are many engineers, particularly those belonging to the old school, and such as have not the least knowledge of the elementary principles of mechanics, who will not admit its utility; who, because such men as Telford, Brindley, George Stephenson, and many others, have risen to eminence by the mere force of their talents, unfettered by, what they term, college knowledge, think that they may also jog on on the "thumb of rule" system. And yet, how frequently have I seen these pseudo-engineers, these practical men, who will not look into a book, for fear it should destroy the originality of their conceptions, fall into the greatest errors from the want of such knowledge. I shall merely state one instance. A resident engineer of one of our railways proposed a plan for strengthening a timber bridge on the line, and in order to test the efficiency of his improvement, made a model of the bridge on the scale, if I recollect rightly, of one inch to the foot; he found that the model would support a certain weight, and thence argued in a truly practical manner, that as the bridge was twelve times the model, it would support twelve times the weight! Thus satisfactorily establishing the utility of his proposed improvement. To return to the question to be solved. If we omit the consideration of the deflection of the beam, the result will be simple and sufficiently correct for practical purposes, and the problem in question may easily be reduced to that of finding the dimensions and form of a beam resting loosely on two supports, necessary to sustain a given weight, (in this instance 42 tons,) placed at the centre of the beam.

Your correspondent states that he found upon experiment, that a bar iron, loaded, as he describes, broke near the two supports; this certainly is strange, and contrary to what we should expect theoretically and practically; for it is evident that the beam between the two supports is more curved at the centre than near the supports, and consequently the strain, being measured by the tension of the fibres, must be greatest in the centre, and gradually diminish to the point of support. I have several times repeated his experiment on a small scale, using, however, wood instead of iron, and have always found that the wood broke in the centre between the supports; of course with the same proportion of external and internal parts mentioned by your correspondent.

It is also clear, from the principle of the lever, that the strain at the centre of the beam, is the same as that produced by a weight of 42 tons placed there, except that the action is reversed: the upper side of the beam will now be compressed in place of being extended, and the under side extended instead of being compressed. If what I have advanced be correct, as I believe, it will result that the best form to give to the beam is the parabolic; that is, the depth of the beam should be greatest at the middle point and diminish at the ordinates of a parabola towards the supports. As the reasons for assuming this form to be the best, are given in all works on the strength of materials, it would be useless to repeat them here. It is generally considered best to have the curved side of the beam upwards in such a case, but as in this example the action is reversed, it follows that it would be advisable to have the curved side downwards. As your correspondent only states the proportion of the distances of the weights from the points of supports to that between them, it is impossible to give the exact dimensions. I have not thought it necessary to give a diagram, as I believe, this explanation may be easily understood from the description, and by referring to that given by your correspondent.

If no better attempt to solve this problem be offered, you will oblige me by inserting this letter.

I remain Sir,
Your obedient servant,
London, Jan. 10th, 1843. T. F.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

Dec. 19.—J. Shaw, Esq., in the Chair.

Mr. Fowler, Hon. Sec., on presenting a plan for rebuilding that portion of Hamburgh, lately destroyed by fire, from M. Chateauneuf, mentioned as a gratifying circumstance, that our countryman, Mr. Lindley, the engineer, had been appointed by the senate to superintend, in part, the rebuilding of the city.

Mr. Godwin read a paper on Tournay Cathedral, which was partly given in last month's *Journal*, and the continuation in the present number.

Jan. 9.—Charles Barry, Esq., V. P., in the Chair.

A paper was read "*On a new mode of constructing the Flues of Chimneys,*" by Mr. Moon, surveyor, explaining an improvement in the construction of flues, of a circular form, of different sizes, from 8 to 14 inches in diameter; the bricks are arranged in courses, carried up and bonded in the thickness of the wall.

"*Description of the Testimonial to the late Sir Harry Burrard Neale,*" erected at Lymington, communicated by Mr. Draper, of Chichester, the architect. It consists of an obelisk, 76 feet high, constructed of Dartmoor granite, standing on a pedestal 18 feet high, the total cost is about £1,400.

Mr. Sylvester's process was described "*for rendering stone, brick, and other absorbent materials impervious to water.*" It consists of two solutions, the first a solution of soap, the second of alum; the brick or stone is first dipped in the solution of soap, and afterwards in the alum, or the solution may be applied with a brush. By the combination of the two solutions, a chemical action takes place, which fills the pores and resists the action of water and moisture. Colouring matter may be introduced into the solutions, and give them any tint that may be desired.

Mr. Billings introduced his "*Illustrations of a mode of striking Gothic tracery;*" they were principally selected from the old choir of Carlisle Cathedral, which was repaired in 1764. The principle upon which most of the varieties of the tracery in this cathedral were formed, was by the combination of curves all having their centres in the same series of lines, formed by dividing a square into four parts each way. The interstices were afterwards filled up by quatrefoil and trefoil ornament, but the main curves are all formed on the above principle. Mr. Billings introduced a fine specimen of tracery, described by circles struck from every intersection of the lines within the square as centres.

Jan. 23.—T. L. Donaldson, Esq., in the Chair.

A letter was read from Herr F. Eisenlohr, Professor, acknowledging the honour of being elected an honorary and corresponding member of the Institute; this letter contains some excellent remarks which we have been permitted to extract.

"I shall esteem it," says Herr Eisenlohr, "a great honour to be united in closer intimacy with your Institute, by the communication of anything relating to the profession. Such an intercourse and reciprocity among the architects of different countries is much to be wished for at the present time, which is principally distinguished from all previous epochs in the history of architecture by its want of unity. Attempts have been made for some time past to remedy this by imitations of the ancient Greek and Roman styles of architecture; and up to the present day many architects are repeating with various talent and success, the attempt to introduce those styles into the present edifices—some, even the imperfect conception of them, called by the French *la Renaissance*. On the other hand, in many places in Germany, a different course has been adopted, which, being partly suggested by the revival of a more christian spirit, partly by the patriotic feeling excited by the French revolution, leaned more to the christian architecture of the middle ages at home. This two principal divisions, each with their varities, stand opposed to one another here in Germany, and carry on, as it were, a contest in secret. The present age is engaged in seeking a something which at present does not exist, viz., unity in a sort of universal architecture. It seems to me, that no immediate and direct imitation in any style of architecture already existing, complete in itself, will lead to the desired result as long as the present age demands its rights, and the existing state of society requires something arising more from its own nature. When I consider also that hitherto in our art we have acted in a manner too little abstractive and scientific, and have *imitated* too much, still, on the other hand, it is not to be denied that we cannot and ought not to disregard history and its effects, that we must have some point in history at which to begin a root, from which a new stem may shoot up into blossom as from the soil of the present. It is quite clear that here also theory and history must go hand in hand, whereby we must with *consciousness* attain to that new and unprejudiced position which, in childlike innocence, unconsciously existed at the commencement of all previous epochs in art. The difference between our age and its problem, as regards architecture, and indeed every branch of the arts, consists in this that we ought to strive, so to say, with manly innocence, with manly knowledge and power, to attain to that point at which former periods in art have in their infancy begun of their own accord. Where there is nothing but an empty and groundless adherence to forms, where architectural fallacy and pretension, or a certain coquetterie is manifested, there an art of a peculiarly creative nature can never be looked for. It is true that many grand buildings have recently been erected in the Roman, Grecian, and so called Byzantine and Gothic styles, as, for instance, particularly at Munich. But they all want the enlivening principle of belonging to the present, and are only silent records of bygone styles of architecture. In the same way that we collect pictures of different schools in galleries, so King Louis has collected buildings of all possible periods; and as he had not got them at Munich, neither could he transport them thence from other parts; he had them built, and thus made a grand collection of buildings at Munich, but which is still deficient in historical authority. If, therefore, we would draw a comparison, we must say that the modern collection of buildings at Munich is, as far as regards the arts, worth about as much as a picture gallery containing a number of more or less successful copies from different masters and schools. If it be true that the spirit of the times is truly expressed in its buildings, that the architecture of every period is, as it were, a fossilized history, future generations will say that the present period was utterly devoid of character. By means of a more intimate acquaintance with the history of architecture, we have been provided with a vast quantity of subject matter, which has hitherto quite overwhelmed us, from its variety and quantity, so that we were quite robbed of our senses. Of this we must first get the mastery, and impelled by a careful observance, as well as by an artistical and inventive spirit, regain our consciousness, without at the same time suffering the experience of history to remain useless. We must, on the one hand, investigate from a theoretical and scientific position, how far our architecture and its elements answer to the conditions of its purpose, of the building materials, climates, and so forth; and must, on the other hand, in looking back upon history, endeavour to find some point which presents constructions and forms similar to those which result from our abstract investigations, and thus a fruitful germ may be found for a modern and, in itself, harmonious style of architecture—a style which would gradually come into general use, and supersede all the lifeless imitations and mere whimsical charges of fashion. In this, it appears to me, consists the great architectural problem of the present age, which can only be solved by united efforts."

Report *on the Marbles from Lycia.*

A report was read from the committee appointed by the Institute to examine the articles that were recently discovered by Mr. Charles Fellowes amongst the ruins of Xanthus, an ancient city in Lycia, in Asia Minor, and lately deposited in the British Museum. Mr. Fellowes explained to the committee "that the tomb is situated on the side, on the slope of a hill, in the old town of Xanthus, consisted of a square shaft in one block, weighing about 80 tons, and 17 feet high. This shaft, which rested on a base or plinth rising six feet from the ground on one side, and the other rising but little above the present level of the earth, was surmounted by the bas-relief in question, the opposite sides of the relief being respectively 8 feet $1\frac{1}{2}$ inches, and 7 feet 6 inches long making a total length of 31 feet 9 inches. It consisted of four angular and four central blocks of marble, each 9 inches thick and 3 feet 5 inches high. A kind of chamber was soon formed in the top of the monument about 7 feet 6 inches high, and 7 feet by 6. This was covered by a single block of marble forming the cornice, and hollowed out in the inside soffit so as to present the appearance of a beam and caissons. Mr. Fellowes considers the subject of the sculptures to represent the legend of the daughters of King Pandarus carried away by the harpies. There are also five figures, male and female, seated on chairs, which are evidently intended to be represented as made of bronze; on these chairs are very perceptible traces of a brownish tint approaching to red, showing that the ornament was indicated by colour, even without the outline being carved.

The figures are about an inch and a half in relief, and in many parts there are patches of blue colour on the ground, particularly on the undercutting of the hair, and especially where the recesses are protected by the overhanging tenia of the frieze, forming the top of the blocks. A portion of this blue colour had been taken off by Mr. Hawkins, and submitted to a chemical analysis by Dr. Faraday, who reported that "The substance is a mixture of wax with a pulverized blue smalt, coloured by cobalt, the smalt being in rather coarse patches; when the wax is charred away, each piece is seen by a moderate magnifier as a small fragment of glass."

On referring to the analysis of Egyptian blue colour by Dr. Ure, given in the 3rd vol., pp. 301—3 of Sir T. Gardner Wilkinson's work on the manners and customs of the ancient Egyptians, there appears to be a great analogy in the composition of this blue and that described by Sir J. Wilkinson; as in the Egyptian specimen the blue pigment scraped from the stone is a pulverulent blue glass.

On the edge of the crest of a helmet were also collected some remains of a bright crimson red which have not yet been analyzed.

On the whole, the committee are of opinion that the appearances which they witnessed are sufficient to warrant their conclusion, that the ground throughout was painted blue, so as to give relief to the figures. Some other parts also had colour, but to what extent the rough state of the surface of the marbles did not enable the committee to ascertain.

The character of the sculpture of the figures denotes a very remote period of art, and it is, to a certain degree, rude; but the forms and embellishments of the bronze chairs are extremely refined, and betoken a class of art not unlike that of the triple temple in the Acropolis of Athens.

When the other marbles and fragments brought from Xanthus have been removed into the upper halls of the Museum, the committee will proceed with their examination on this interesting subject, and they will, if necessary, report to the Institute the result of their inquiries.

The Chairman, in consequence of the unavoidable absence of Mr. Britton, who was to have read a paper this evening, was requested by the secretaries to supply a paper, which he readily acceded to with his usual promptness in all similar difficulties; the subject of the paper was "*On the ruins of the city of Ani, in Armenia,*" but as we are likely to give the paperin full next month, we defer giving any abstract.

The meetings for February will take place on Monday 6th, and 20th, at 8 o'clock.

INSTITUTION OF CIVIL ENGINEERS.

Jan. 10.—James Walker, Esq., President, in the chair.

This was the first meeting of the session, and was occupied by a discussion on a paper by Mr. Davison, describing the sinking of the deep well at Messrs. Truman and Co.'s, brewery, which was read at the close of last session. See *Journal*, Vol. 5, 1842, page 420.

Jan. 17.—The President in the Chair.

This was the annual general meeting of the Society, and was occupied in reading the report of the council, the election of the council and the distribution of the prizes; we must defer until next month a report of the proceedings when we hope to be able to give them in full.

DESTRUCTION OF THE ROUND-DOWN-CLIFF BY GUNPOWDER.

[We are partly indebted for the accompanying report to the *Times*, and through the kindness of two professional friends, who were on the spot and witnessed the explosion, we have been enabled to give considerable additional information; and have also added a rough sketch of the cliff, that was hastily taken, just before and after the explosion took place.]

Dover, Jan. 26th, 1843.

You will not be surprised to hear that the announcement that an explosion of 18,000 lb. of powder was to be made in the Round Down Cliff this afternoon brought an influx of strangers into this town; still, though considerable, it was not so large as I had expected. Curiosity was, I think, paralyzed by a vague fear of danger, which kept some thousands at home who might have witnessed it, as the event turned out, without the slightest shock to their nervous system. The experiment succeeded to admiration, and, as a specimen of engineering skill, confers the highest credit on Mr. Cubitt, who planned, and on his colleagues who assisted, in carrying it into execution.

Everybody has heard of the Shakspeare Cliff, and I have no doubt that a majority of your readers have seen it. I should feel it a superfluous task to speak of its vast height were not the next cliff to it, on the west, somewhat higher. That cliff is Round Down Cliff, the scene and subject of this day's operations. It rises to the height of 375 feet above high-water mark, and was, till this afternoon, of a singularly bold and picturesque character. To understand the reasons why it was resolved to remove yesterday no inconsiderable portion of it from the rugged base on which it has defied the winds and waves of centuries, I must make your readers acquainted with the intended line of railway between Folkestone and this place.

At Folkestone there will be a viaduct of great height and length. Then there will be a tunnel, called from a martello tower near it, the Tower Tunnel, one third of a mile in length. Then comes a cutting through the chalk of two miles in length, called Warren's Cutting. Then comes the Abbott's Cliff tunnel, one mile and a quarter in length, and now half finished, although only commenced on the 16th of August last. From the Abbott's Cliff tunnel to the Shakespeare Cliff tunnel the railroad will be under the cliffs close to the sea, and protected from it by a strong wall of concrete two miles long, and with a parapet of such a height as will not preclude passengers from the splendid marine view which lies under them. Now it was found that when a straight line was drawn from the eastern mouth of the Abbott's Cliff tunnel to the western mouth of the Shakespeare tunnel, there was a projection on the Round Down Cliff which must be removed in some way or other to insure a direct passage. That projection, seen from the sea, had the appearance of a convex arc of a circle of considerable diameter. It is now removed, and some idea of its size may be formed from the fact that a square yard of chalk weighs two tons, and that it was intended by this day's experiment to remove 1,000,000 tons. The Shakspeare tunnel is three-quarters of a mile long, and it is about the same distance from that tunnel to the town of Dover.

Having premised thus much as to the locality of Round Down Cliff, I now proceed to describe, as briefly as I can, the means employed to detach from it such an immense mass of solid matter. A horizontal gallery T. Fig. 3, extended for about 100 yards parallel with the intended line of railway, from which cross galleries were driven from the centre and extremes. At the end of these cross galleries shafts were sunk, and at the bottom of each shaft was formed a chamber, 11 feet long, 5 feet high, and 4 feet 6 inches wide. In the eastern chamber were deposited 5000 lb. of gunpowder, in the western chamber 6000 lb., and in the centre chamber 7000 lb., making in the whole 18,000 lb. The gunpowder was in bags, placed in boxes. Loose powder was sprinkled over the bags, of which the mouths were opened, and the bursting charges were in the centre of the main charges. The distance of the charges from the face of the cliff was 70 feet at the centre and about 55 feet at each end. It was calculated that the powder, before it could find a vent, *must* move 100,000 yards of chalk, or 200,000 tons. It was also confidently expected that it *would* move 1,000,000 tons.

The following preparations were made to ignite this enormous quantity of powder;—At the back of the cliff a wooden shed was constructed, in which three electric batteries were erected. Each battery consisted of 18 Daniels' cylinders, and two common batteries of 20 plates each, to which were attached wires which communicated at the end of the charge by means of a very fine wire of platina, which the electric fluid as it passed over it, made red-hot, to fire the powder. The wires covered with yarn were spread upon the grass to the top of the cliff, and then falling over it were carried to the eastern, the centre, and the western chamber. Lieutenant Hutchinson, of the Royal Engineers, had the command of the three batteries, and it was arranged that when he fired the centre, Mr. Hodges and Mr. Wright should simultaneously fire the eastern and the western batteries, to ensure which they had practised at them for several previous days. The wires were each 1,000 feet in length, and it was ascertained by experiment that the electric fluid will fire powder at a distance of 2,300 feet of wire. After the chambers were filled with powder, the galleries and passages were all *tamped* up with dry sand, as is usually the case in all blasting operations.

At 9 o'clock in the morning a red flag was hoisted directly over the spot selected for the explosion. The wires were then tested by the galvanometer, the batteries were charged, and every arrangement was completed for firing them.

It was arranged that the explosion should take place at 2 o'clock; at that time there was an immense concourse of people assembled. In a marquee erected near the scene of operation, for the accommodation of the directors and distinguished visitants, we observed among the number assembled, Sir John Herschell, General Pasley, Col. Rice Jones, Mr. Rice, M.P., Professors Sedgwick and Airy, the Rev. Dr. Cope, and there was also a strong muster of engineers, among whom were Mr. Tierney Clark, Mr. John Braithwaite, Mr. Charles May, Mr. Lewis Cubitt, and Mr. Frederick Braithwaite; the engineers and directors of the Greenwich, Croydon, Brighton, and South Eastern Railways, besides numerous foreigners of eminence.

At 10 minutes past 2, Mr. Cubitt, the company's engineer in chief, ordered the signal flag at the western marquee to be hoisted, and that was followed by the hoisting of all the signal flags. A quarter of an hour soon passed in deep anxiety. A number of maroons, in what appeared to be a keg, was rolled over the cliff, and on its explosion with a loud report, all the flags were hauled down. Four more minutes passed away, and all the flags except that on the point to be blasted were again hoisted. The next minute was one of silent, and breathless, and impatient expectation. Not a word was uttered, except by one lady: who, when too late, wished to be at a greater distance. *Galeatum sero duelli pœnitet.* Exactly at 26 minutes past 2 o'clock a slight twitch or shock of the ground was felt, and then a low, faint, indistinct, indescribable moaning subterranean rumble was heard, and immediately afterwards the bottom of the cliff began to belly out, and then almost simultaneously about 500 feet in breadth, with reference to the railway's length of the summit began gradually to sink.

There was no roaring explosion, no bursting out of fire, no violent and crashing splitting of rocks, and what was considered extraordinary, no smoke whatever; for a proceeding of mighty and irrepressible force, it had little or nothing of the appearance of force. The rock seemed as if it had exchanged its solid for a fluid nature, for it glided like a stream into the sea, which was at a distance of about 100 yards—perhaps more—from its base, tearing up the beach in its course, and forcing up and driving the muddy substratum together with some debris of a former fall, violently into the sea, and when the mass had finally reached its resting place a dark brown colour was seen on different parts of it, which had not been carried off the land; the shattered fragments of the cliff are said to occupy an area of 15 acres, but we should judge it to be much less. I forgot to minute the time occupied by the descent, but I calculate that it was about four or five minutes. The first exclamations which burst from every lip was—"Splendid, beautiful!" the next were isolated cheers, followed up by three times three general cheers from the spectators, and then by one cheer more. These were caught up by the groups on the surrounding downs, and, as I am informed, by the passengers in the steam boats. All were excited—all were delighted at the success of the experiment, and congratulation upon congratulation flowed in upon Mr. Cubitt for the magnificent manner in which he had carried his project into execution.

As a proof of the easy, graceful, and swimming style with which Round Down Cliff, under the gentle force and irresistible influence of Plutus and Pluto combined, curtseyed down to meet the reluctant embraces of astonished Neptune, I need only mention that the flagstaff, which was standing on the summit of the cliff before the explosion took place, descended uninjured with the fallen debris.

No fossil remains of the slightest importance were brought to light, which was a matter of disappointment to many. A very few even of the most ordinary character were found among the mass. which it may well be imagined was soon after the explosion, teeming with the curious multitude from the cliffs above anxious to obtain some relic of the event.

On examining the position occupied by the debris of the overthrown cliff, we were much pleased to find it more favourably disposed than we could have conceived possible. Instead of occupying the site of the proposed railway at the foot of the cliff, it had by its acquired velocity slid past it. and left comparatively little indeed to be removed. At some considerable distance from the cliff, the fragments appeared to be heaved up into a ridge. higher than any other part, forming a small valley towards the cliff, and another seaward, beyond which a second ridge appeared. when it finally slopes off towards the sea. The chalk was by no means hard, and appeared thoroughly saturated with water. The great bulk of the fragments ranged from about 2 to perhaps 8 or ten cubic feet, although we observed a vast number of blocks, which contained from two to three cubic yards and upwards, one of which was driven some distance into the Shakespeare Tunnel, without doing injury to the brickwork. There was very little, indeed, of what might be termed rubbish in the mass.

Previous to the explosion, we had heard it stated that about a million yards were expected to be detached; indeed the Railway Times so stated it, on the 21st ultimo, apparently from authority, and after the explosi n took place, it was publicly asserted by one of the officials, that three quarters of a million of cubic yards had come down. Now, on cubing the stated dimensions of the mass, which were given as under 300 feet in height by, say 50 feet longer than the gallery, which would therefore be 350 feet, by an average thickness or depth from the face of the cliff of 60, we shall have 233,333 cubic yards; but as the present face slope of the cliff is greater than before, the average thickness perhaps might be increased to 75 feet, which would make the quantity 291,666 cubic yards, from this is to be deducted 50,000 yards, the estimated quantity to be now shifted in forming the road, we shall then have 30,000 yards effectively removed by the expenditure of one ton of powder. We understand that Mr. Cubitt, the engineer, afterwards stated that a saving of six months' work, and £7000 expenditure was effected by this blast. Now allowing 6*d* per yard for the removal of the quantity now required to be shifted, which would amount to £1250, and £500 for the powder used in the blast, the cost of forming the galleries, tamping, &c. &c., we shall find that this mass has been removed at a cost of 1.44 pence per yard. Again, taking Mr. Cubitt's statement, that a saving has been effected of £7000. to which, if we add the £1750, expenditure by the present plan, we shall find that he estimated the cost of removal by hand labour, at rather less than 7½*d*. per yard.

We felt an interest in examining the beds and fissures of the chalk in the neighbourhood of this blast, which clearly indicated that the plan of removal adopted by Mr. Cubitt, was not only the cheapest, but the safest method which could have been adopted. The vertical fissures which here traverse the chalk appear to lie pretty nearly parallel, and at a slope perhaps of one-fifth to one-tenth to one. It was in one of these fissures that the whole mass parted and slipped down, on which we believe it had set previously, no doubt brought about by the infiltration of water more than the sapping of the base by the sea. So treacherous indeed was this chalk, that if we are rightly informed, a mass equal nearly in bulk to that blasted on Thursday came down unexpectedly some time since in the night time, burying in its ruins a watchman or foreman belonging to that part of the line. In the zigzig gangways cut along the face of the cliff, to enable persons to ascend to the summit—this sliding of the chalk where those vertical fissures are intersected, appears very frequently, inspiring the passer-by with a feeling of great insecurity. How far the water might be intercepted, or otherwise be prevented from filtering through these fissures is a question of great importance, and would not, we think, be one of difficult remedy. It also becomes a matter of interesting inquiry as to the effect which a lesser qantity of powder would have had, deposited and fired in the same manner. Would it only have made the mass insecure, or caused a partial sliding down, rendering it then more difficult of removal by hand than at first? The proportion of powder which Mr. Cubitt employs in his blasting operations we understand is determined thus: "The cube of the line of least resistance in feet, gives the quantity in half ounces;" but in this case there does not appear to have been any such quantity employed, though much more than heretofore is found necessary in usual blasting operations. Perhaps the most curious circumstance, connected with the operation, was the apparent absence of shock on the firing of the charge on some spots in the immediate vicinity, while at other, far more distant, it was clearly perceptible. Thus where the batteries were placed, those in charge of them thought the charge had missed fire, from their being insensible to any shock, while at five times the distance along the face of the cliff, it was clearly felt. But even along the face of the cliff it was very evident that the shuck was felt by some and not by others, though standing within a few yards of each other.]

Neapolitan Steamers.—We lately had the pleasure of attending the trial of two steam vessels, named the *Rondine* (Swallow), and the *Antelope*, built at Northfleet, by Mr. Pitcher, for the revenue service of his Neapolitan majesty. The engines of both vessels are manufactured by Messrs. Boulton, Watt, and Co. These vessels are of similar dimensions, in fact built from the same drawing, and are in length between perpendiculars, 100 feet; keel for tonnage, 90 feet, 5 inches; extreme breadth, 16 feet; moulded breadth, 15 feet 5 inches; depth in hold, 9 feet 6 inches; tonnage, O.M., 123$\frac{1}{94}$; displacement as launched, 65 tons; ditto, complete with 25 tons of coals, 115 tons. Draft, at this, 7 feet 3 inches. Immersed section, 91 feet. Speed at measured mile = 9 miles per hour. Although the *Rondine* and *Antelope* are of the same capacity, they differ in the construction of their motive powers: the former, the *Rondine*, having beam engines, the *Antelope*, oscillating or vibrating cylinder engines, both of the power of 40 horses. Cylinders $26\frac{3}{4}$ in. diameter, stroke, 2.6, and 34 strokes per minute. The beam engines are of the usual construction, as designed by Boulton and Watt in 1818. The various parts are reduced in strength as experience and improved manufacture dictates; we perceive they have in this case abolished the headstock framing, substituting pillars and an entablature, secured longitudinally by strong deck or paddle beams, they are continued through the side, supporting the ends of the paddle shafts, so that they have no connexion with the spring-beam or frame of the paddle-boxes, thereby preventing tremulous motion. This arrangement is by no means new, yet greatly to be recommended and will shortly be applied to a vessel of 300 horse power. The oscillating engines of the *Antelope*, in *arrangment*, are similar to those of the *Virago*, published in the *Journal*, June 1841, Vol. IV., each engine having its air-pump and condenser—the former worked by a small beam connected with the cranked intermediate shaft. It may be mentioned as an argument in favour of oscillating engines (of moderate power), that in these cases there is a saving of five feet in length of engine-room, and in weight of about six tons. These engines occupy a space of 10 feet athwart, and five feet fore and aft. The small amount of the former arises from the combination of the parts, and must be advantageous in its application to vessels of narrow beam. The boilers in both cases are of the common flue kind, weighing $7\frac{1}{2}$ tons; or, with its apparatus and water (the latter five tons), $14\frac{1}{2}$ tons; the engines weigh 13 tons, making a total of $27\frac{1}{2}$ tons complete. Both these vessels are fitted with a disengaging apparatus for the paddle wheels, so that they may be connected with, or detached from, the engines at pleasure, which, as well as the engines of the *Antelope* are the subjects of a patent lately granted to Mr. James Brown, of the firm of Boulton, Watt, and Co.

THE GREAT NORTHERN STEAM-SHIP.—This magnificent ship arrived off Blackwall at the beginning of last month, and has since taken up a berth in the East India Import Dock. The Great Northern has been built within the last 12 months at Londonderry, by Captain Coppin, of that place. She is a fine specimen of naval architecture. She is fitted with Mr. F. P. Smith's patent screw propeller. Her dimensions and power are given in the *Journal* for July last. p. 243, Vol. V., under the head of "The *Monster* Steam-Ship."

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM DECEMBER 28, 1842, TO JANUARY 28, 1843.

Six Months allowed for Enrolment, unless otherwise expressed.

Alonzo Grandison Hull, of Clifford Street, Middlesex, doctor of medicine, for "*improvements in electrical apparatus for medical purposes, and in the application thereof to the same purposes.*"—Sealed December 28.

Thomas Thompson, of Coventry, weaver, for "*improvements in weaving figured fabrics.*"—Dec. 28.

Henry Crosley, of the city of London, civil engineer, and George Stevens, of Limehouse, gent., for "*improvements in the manufacture of sugar, and the products of sugar.*"—Dec. 28.

Edward Thomas, Lord Thurlow, of Ashfield Lodge, Ipswich, Suffolk, for "*an improvement or improvements on bits for horses and other animals.*"—Dec. 29.

Benjamin Bailey, of Leicester, frame-smith, for "*improvements in machinery employed in the manufacture of stockings, gloves, and other framework knitted fabrics.*"—Dec. 29.

John Stephen Bourlier, of Sherborn Street, Blandford Square, engineer, for "*improvements in machinery used in printing calicoes, silks, paper hangings, and other fabrics.*" (A communication.)—Dec. 29.

Joseph Rock, Jun., of Birmingham, factor, for "*improvements in the construction of locks,*"—Dec. 29.

Henry Samuel Rush, of Sloane Street, mechanic, for "*for improvements in apparatus for containing matches for obtaining instantaneous light.*"—Dec. 29.

Baron Victor de Wydroff, of old Bracknell, Berkshire, for "*improvements in the construction of railways and in wheels to run on railways, and in apparatus for clearing the rails.*"—Dec 29.

John Bishop, of Poland Street, Westminster, jeweller, for "*improvements in apparatus for portioning steam power; and also improvements in plugs, cocks, or taps for steam gases and liquids.*"—Dec. 29.

Crawshay Bailey, of Nant-y-Glo iron works, Monmouth, Esq., for "*improved constructions of rails for tramways and railways.*"—Jan. 11.

James Harvey, Jun., of Regent Street, goldsmith, for "*improvements in steam engines.*" (A communication.)—Jan. 11.

William Ritter, of 106 Fenchurch Street, gentleman, for "*improvements in crystallizing and purifying sugar.*" (A communication.)—Jan. 11.

Julian Edward Disbrowe Rodgers, of Upper Ebury Street, chemist, for "*improvements in the separation of sulphur from various mineral substances.*"—Jan. 12.

William John Leat, of Clapham, builder, for "*an improved mode of constructing floors and roofs.*"—Jan. 12.

Pierre Armande Comte de Fontain le moreau, of Skinner's Place, Sise Lane, for "*process or processes of combining clay with some other substances for the producing of a certain 'ceramic paste,' capable of being moulded into a variety of forms, and the application thereof to several purposes.*" (A communication.)—Jan. 14.

James Harvey, of Bazing Place, Waterloo Road, timber merchant, for *improvements in paving streets, roads, and other places.*" (Partly a communication.)—Jan. 14.

William Snell, of Northampton Square, gentleman, for "*improvements in machinery for the manufacture of farina.*"—Jan. 14.

Nathaniel Card, of Manchester, candle-wick manufacturer, for "*improvements in the manufacture of candlewicks, and in the machinery or apparatus for producing such manufacture.*"—Jan. 14.

Henry Hussey Vivian, of Singleton, Glamorgan, Esq., and William Gossage, of Birmingham, manufacturing chemist, for "*improvements in heating or reducing ores of zinc; also for improvements in furnaces to be used for reducing ores of zinc, part of which improvements are applicable to other furnaces.*"—Jan. 14.

James Hamer, of Wardour Street, engineer, for "*improvements in propelling vessels.*"—Jan. 19.

Thomas, Earl of Dundonald, of Regent's Park, for "*improvements in rotatory or revolving engines, and in apparatus connected with steam engines, and propelling vessels.*"—Jan. 19.

Joseph Kirkman, Jun., of Soho Square, pianoforte manufacturer, for "*improvements in the action of pianofortes.*"—Jan. 19.

Thomas William Bennett, of Gray's Inn Road, timber merchant, for "*improvements in paving or covering roads, streets, and other ways and surfaces.*"—Jan. 19.

Luke Hebert, of Dover, civil engineer, for "*improvements in machines for grinding, and for dressing or sifting grain, and other substances.*"—Jan. 19.

William Bates, of Leicester, fuller and dresser, for "*improvements in the dressing and getting up of hosiery goods, comprising shirts, drawers, stockings, socks, gloves, and other looped fabrics, made from merino, lambs' wool, worsted, cotton, and other yarns, and in machinery for raising the nap or pile in the same.*"—Jan. 6.

Thomas Sunderland, of Albany Street, Regent's Park, Esq., for "*improvements in moving floating bodies through water and air, and in accelerating the flow of water, air, and other fluids, through shafts, pipes, and other channels.*"—Jan. 19.

Uriah Clarke, of Leicester, dyer, for "*improvements in framework-knitting machinery, and a new kind of framework-knitted fabric.*"—Jan. 21.

Frederick Albert Winsor, of Lincoln's Inn Fields, barrister-at-law, for "*new apparatus for the production of light.*" (A communication.)—Jan. 26.

Charles Frederick Bielefeld, of Wellington Street, North Strand, papier-maché manufacturer, for "*improvements in suspending or hanging swing looking glasses and other articles requiring like movements.*"—Jan. 26.

William Palmer, of Sutton Street, Clerkenwell, manufacturer, for "*improvements in the manufacture of candles.*"—Jan. 26.

Henry Chapman, of Arundel Street, Strand, for "*a fabric for maps, charts, prints, drawings, and other purposes.*"—Jan. 26.

Frances M'Gretrick, of Ernest Street, St. Pancras, artisan, and Matthew Bailey Tennant, of Henry Street, Regent's Park, gentleman, for "*improvements in apparatus for preventing engines and carriages from going off railways, and for removing obstructions on railways.*"—Jan. 26.

Edward Smallwood, of North Lodge, Hampstead, gentleman, for "*improvements in covering roads, ways, and other surfaces.*"—Jan. 26.

Robert Goodacre, of Ullesthorpe, Leicester, gentleman. for "*improvements in weighing apparatus applicable to cranes or other elevating machines, whereby the weight of goods may be ascertained while in a state of suspension.*"—Jan. 26.

James Boydell, Jun., of Oak Farm Works, Dudley, Stafford, iron master, for "*improvements in the manufacture of metals for edge tools.*"—Jan. 26.

George Parker Bidder, of Great George Street, Westminster, civil engineer, for "*an improved mode of cutting that kind of slates, commonly called roofing slates, though sometimes used for other purposes.*"—Jan. 26.

William James Greenstreet, of Blackfriars' Road, gentleman, for "*improvements in machinery or apparatus for producing or obtaining motive power.*"—Jan. 26.

Joseph Kirby, of Banbury, Oxford, gentleman, for "*improved apparatus for manufacturing bricks, tiles, and other articles from clay or earthy materials.*"—Jan. 26.

George Phillips Bayly, of 146, Fenchurch Street, brush maker, for "*improvements in brushes.*"—Jan. 26.

Henry Phillips, of Exeter, chemist, for "*improvements in removing impurities from coal gas for the purposes of light.*"—Jan. 26.

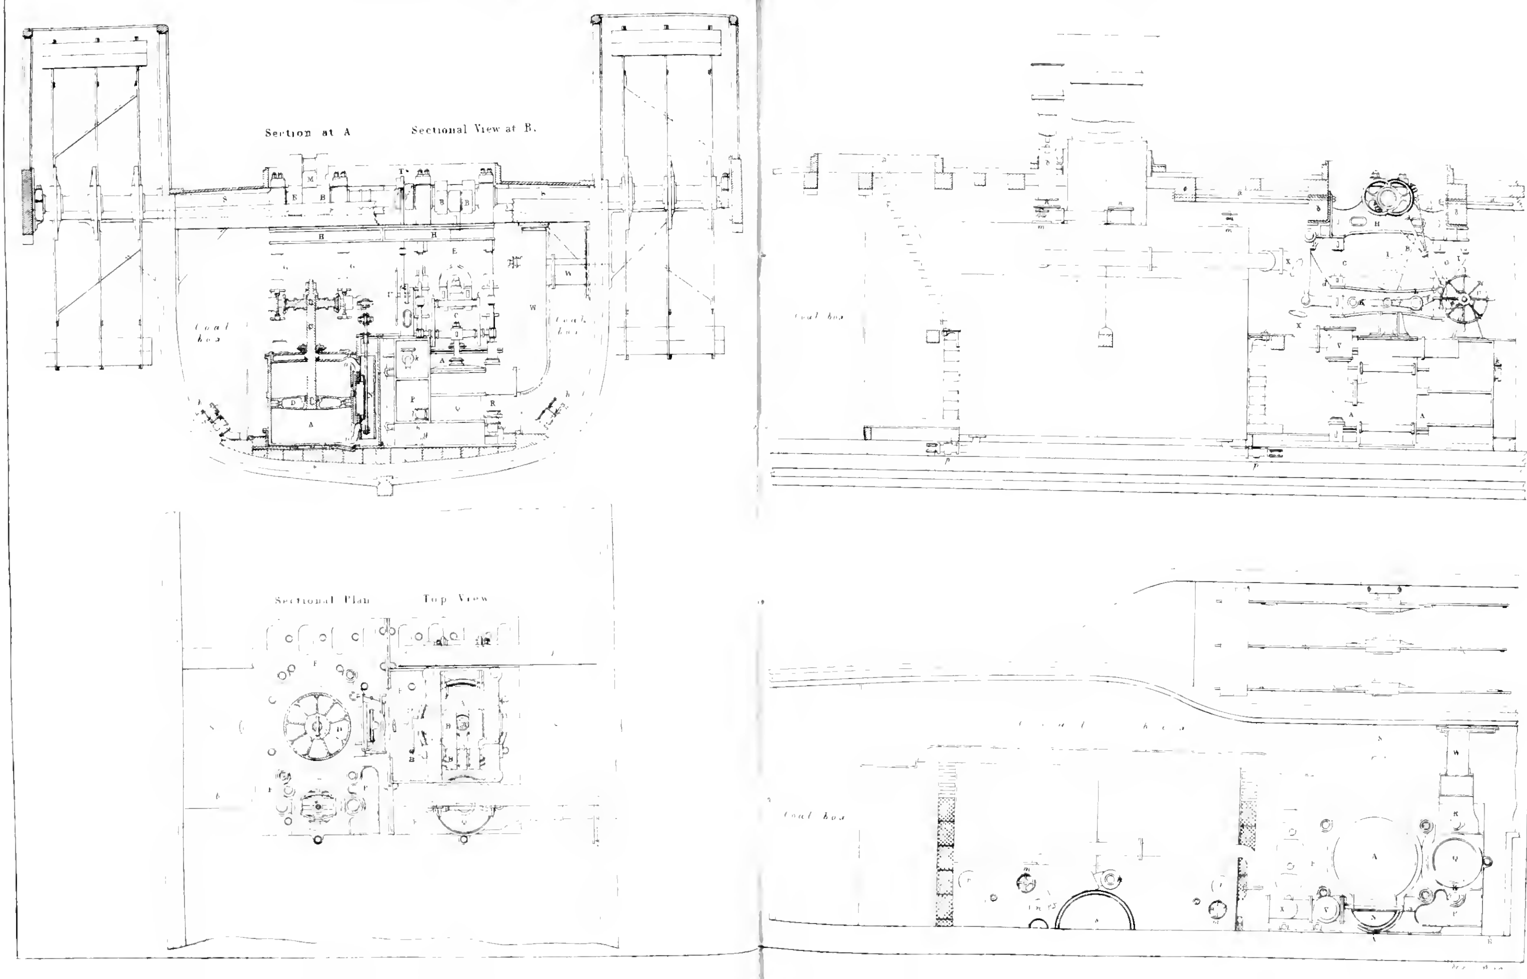
Martyn John Roberts, of Brynycaeran, Carmarthen, Esq., for "*improvements in dyeing wool and woollen fabrics.*"—Jan. 26.

William Weild, of Manchester, Engineer, for "*improvements applicable to window blinds and curtains, part of which improvements are also applicable to doors.*"—Jan. 28.

David Isaac Wertheimber, of West Street, Finsbury Circus, gentleman, for "*improvements in calculating machines, part of which improvements is applicable to purposes where wheelwork is required.*"—Jan. 28.

John Barrow, of East Street, Manchester Square, engineer and smith, for "*improvements in the manufacture and hanging of window sashes.*"—Jan. 28.

Engines of H. M. STEAM SHIP VULTURE of 476 HORSE POWER, By WILLIAM FAIRBAIRN & C? Mill Wall, London



ENGINES OF H. M. STEAM SHIP "VULTURE."

By Wm. Fairbairn & Co., Millwall Works, London.

(With two Engravings, Plates II and III.)

The general arrangement of these engines will be apparent, from an inspection of the accompanying engravings. Their chief peculiarity consists in the arrangement of the parallel motion, and the manner in which it is made available for working the air-pump. The four main parts of each engine, viz., the cylinder, slide valves, condenser, and air-pump, form a square, and thus occupy the least possible area. With a speed of 220 feet per minute, and an effective pressure of 7 lb. on the square inch, according to the regulation of the Admiralty engineer officers, the power will be 238 horses for each engine, or 476 horses collectively. The space occupied by the engines is 12 feet 3 inches fore and aft, and 19 feet athwartships, and the total length of the engine room is 52 feet 8 inches, with boilers calculated for the full power of the engines; and 59 feet 8 inches, with stowage for 440 tons of coal.

The leading dimensions and proportions are as follow—the letters refer to the engravings.

A, Cylinder, 80⅝ in. diameter.
B, Crank, 2 ft. 10½ in. from centre to centre.
Length of stroke, 5 ft. 9 in.
C, Piston Rod, 8¼ in. diameter.
D, Piston, with metallic packing rings, and steel springs.
E, Connecting Rod, 8 ft. 7½ in. long, 10 in. diameter at middle, and 9 in. diameter at ends.
F, F, Base plate, cast in two parts, one for each engine, and firmly joined in the middle. It projects equally on both sides of the crank shaft, and takes hold of the ship for the length of 17 ft. 6 in.
G, G, Wrought Iron Columns, 7 in. diameter, keyed into sockets on the base plate, and rising through sockets cast on the cylinder, to carry the entablature. The sockets on the cylinder are bored out to fit the columns, but allowed to rise or fall with the elongation or contraction of the cylinder.
H, H, Entablature, supported by the wrought iron columns G, G. It is attached by bolts *a a*, to the engine beams *b b*, and these bolts run through to the main paddle-beams *c c*; diagonal trussing being introduced between these beams.
I, I, Wrought iron cross stays, with the sockets *d d* forged in one piece. These sockets are bored out to fit the columns which pass through them, and are fastened with a cotter.
K, Wrought iron stays.
L, Shaft, fixed in a boss on the wrought iron stays K, and on which the beams *e e* vibrate to work the air-pump, these beams being at the same time the radius rods of the parallel motion of the piston rod. On the outer and projecting end of this shaft, the lever *f f* for working the valves also vibrates.
M, Crank Pin, 11 in. diameter.
N, N, Slide Valves, 14 in. length of travel; 8$\frac{9}{16}$ in. breadth of space.
O, O, Cylinder Ports, 40 in. long by 5⅜ in. broad, and ⅝ in. open to the steam when the engine is on the centre; they are opened equally for the ascending and descending strokes, as the engine is balanced by other means.
P, Condenser, cubic contents 103 ft; *g*, foot valve, *h h*, injection pipes with Kingston's valves, *k*, sea injection cock, *l*, bilge injection cock.
Q, Air Pump, 45 in. diameter.
Ditto length of stroke 2 ft. 10½ in.
Air pump rod, cased with brass, 5¾ in. diameter.
R, Feed and Bilge Pumps.
S, Paddle shaft, 15¾ in. diameter of necks.
T, Eccentric.
U, Starting gear, power as 15 to 1.
V, Equilibrium Expansion Valve; *i*, cam for working expansion valve.
W, Waste water pipe and delivery pipe.
X, Steam pipe to each cylinder 17½ in. bore.
Paddle wheels 26 ft. 6 in. diameter to extremity of floats.
Ditto, floats 8 ft. 9 in. long. Each float in two parts, and each part 13 in. broad.
Boilers four in number placed back to back, 23 ft. 2 in. total length, 26 ft. 10 in. total breadth, and 13 ft. high.
m, m, Shut off valves for steam, to connect or disconnect the boilers.
n, n, Safety valves, one on each boiler, with levers in the engine room to ease off the weights.
o, o. Vacuum or reverse valves.
p, p, Blow off cocks, one to each boiler, with Kingston's valves.
r, r, Man-holes to boilers.
s, Chimney, 5 ft. 10 in. diameter, and 44 feet high above steam-chest, with double external casing.
t, Waste steam pipe, 17 in. bore, with internal pipe for condensed water.

A CHAPTER ON CHURCH-BUILDING.

Being Comments on some Opinions thereon recently published.

By George Godwin, F.R.S., &c.

The Anglican church for some years past, if it may be said with ut apparent want of respect, has neglected her duties. Zeal was wanting on the part of her ministers, and luke-warmness, if nothing worse, was the result on the part of the congregations. To remedy this evil, many good and learned men have lately worked sedulously, and have succeeded in raising a very different feeling from that which existed before on the subject. Whether, as is often the case after a violent re-action, an evil of an opposite character may be caused—whether the freshly excited zeal has not, or may not, outrun discretion, it would not become the writer to inquire in this place: his business is simply with one result of the present state of opinion.

With greater attention to the rites and ceremonies of religion, has come, very properly, greater regard for the buildings in which they are celebrated. The text, "Is it time for you, O ye, to dwell in your cieled houses, and this house lie waste?" has been powerfully commented on in numerous places, and has been put forth in various shapes; while at both our Universities, as well as in many other quarters, societies have been established, whereof the clergy are the chief supporters, for the improvement of church architecture, and for the preservation, and the proper restoration, of ancient models. This has led to a corresponding increase of attention to the subject, on the part of the professors of the art; the principles of pointed architecture (the ecclesiastical architecture of our forefathers), have been investigated, and much sounder views have been arrived at than were before general: so that not to mention what has been already done, we may anticipate, without fear of disappointment, an important improvement in every new church that may hereafter be erected.

One of the points dwelt on at considerable length by recent ecclesiological writers, is, the *symbolism* of church architecture, the fact that every ancient ecclesiastical building was intended to convey numerous sacred truths by its form and arrangement,—and the consequent deduction that *ritualism* should be carefully studied by all those who may be called on to design churches.

A general outline of their views in this respect, regarding a church as deduced from ancient buildings remaining to us, may be thus stated. A chancel and a nave are the essential parts of a church; the latter is the representative of the church militant, the former of the church triumphant. The chancel-arch, which defines and separates the two (and is never to be omitted) images the close of our life. The entrance to the sacred structure should be at, or as close to, the west-end as possible, and the font must be placed near it, typical of our entry to the church militant by baptism.

When ailes can be added to the nave, the edifice becomes more perfect, as, apart from the increased accommodation, the three parallel divisions so formed, serve in continuation of the symbolical system, to set forth the Holy Trinity, to which numerous other references are ever found, in the windows and tracery of ancient ecclesiastical buildings. In a cruciform church, the best form, but to be adopted only when funds are plentiful, the four arches at the junction of the nave, chancel, and transept, symbolise that by the writings of the four Evangelists, the doctrine of the cross is taught to the four quarters of the world. Further, on the altar are to appear two candles, to signify that "Christ is a light to lighten the Gentiles, and the glory of his people Israel."

Now, that it is wise and proper to enforce this system so strongly and so constantly as has been done—to render matters of this description all-important—we should be quite unwilling to assert. We would give all "the aid which slackening piety requires;" we would not

> " ———— conceal the precious cross
> Like men ashamed: the sun with his first smile,
> Shall greet that symbol crowning the low pile:
> And the fresh air of incense-breathing morn,
> Shall wooingly embrace it; and green moss
> Creep round its arms thro' centuries unborn."

We would place

> " Our Christian altar faithful to the east,
> Whence the tall window drinks the morning rays;"

We would most worthily adorn the house of God, to render it to the extent of our means fitting for its high purpose—but at the same time we would carefully avoid all proceedings, however agreeable to our temperament, however enticing to us as an artist, which should give undue importance to bricks and stones, and man's inventions and devices, which should increase the number of ceremonial observances, which should threaten to exalt the shadow in the place of the substance, and so lead to a state of things which did once result from such a course, and may result again, notwithstanding the increased amount of information possessed, and the general comparative enlightenment.

Relative to the size of the chancel, the Cambridge writers say, it "should not be less than a third, or more than the half, of the whole length of the church. The larger it is made within the prescribed bounds, the more magnificent will be the appearance of the building."[1] Into this portion of the structure, none but those engaged in the ceremonies are to enter; and here the whole of the service is to be performed with the exception of the sermon. The north side of the chancel-arch is pointed out as the best position for the pulpit. It seems to us, and we say it with the greatest deference, that a deep chancel, such as is here insisted on, however magnificent and striking it may, and does, make a building, is unsuited to the Protestant service as it has been *heretofore* performed. The fact is evident in an examination of the arrangements made in the majority of our cathedrals, wherein, if the service were read in the chancel, so to term it, and the worshippers were confined to the nave, nothing said by the priest at the altar could possibly be heard by them. In ordinary sized parish churches too, if the chancel were one-third the length of the building, and still less if half, the majority of priests would fail to make themselves heard, unless indeed the altar were placed at the west-end of it, with a reredos or screen, to rail off the remainder of the chancel. The use of the rood-screen, still further to separate the laity from the clergy, which is strongly insisted on, would throw an additional impediment in the way. *If it be not necessary* that the service should be heard and understood, and into this inquiry we will not venture to go, then of coruse the objection vanishes. The very occurrence of this question in the mind, however, serves to explain why the architectural works to which we have referred, are termed by some, "engines of polemical theology."

Writers of the Roman Catholic faith insist on the inconsistency of the position held by Protestant divines, who urge this and other opinions relative to the form, arrangement, and decoration of our churches. "The good men who are so earnestly labouring for the revival of Catholic church architecture," says the *Dublin Review*,[2] must be convinced that we must have the Catholic service revived, in the first place, before any real good can possibly be accomplished." This last necessity, (Catholic meaning here *Roman* Catholic,) we deny altogether. The principles of ancient church architecture, as applied to suit one set of circumstances, being studied and understood, may be adapted without difficulty to other, and in this case but slightly modified, circumstances, and made to produce as efficient a result. The remark, however, may possibly be deemed to apply in some degree to those who would bring back all such forms and details as were anciently used, although altogether unsuited to present requirements.

The antiquity alone, of a practice or form (strong as it makes its claim), would hardly seem sufficient authority in all cases for its revival: thus, (to illustrate our meaning from a different source,) the certainty that the practice of burying in churches is of very ancient date, and its consonance with our feelings, are now not deemed by the majority sufficient reasons for its continuance, the injurious tendency of the custom being fully known.

According to recent writers, nothing is to be done that has not been done before. Fearing the ignorance of modern architectural professors, (a little too imperiously stated, be it remarked, by some of the non-professional writers,) the necessity of having a precedent for every tower, and door, and window, and moulding, is insisted on. Design nothing, copy all, is the deduction which forcibly presents itself. "Inspice et fac secundum exemplar quod tibi monstratum est." This course has safety to recommend it, but will hardly effect for posterity, what our forefathers have done for us.

To rid our churches of close pews and lumbering galleries, and to destroy the opinion, that to accommodate the greatest number of people at the smallest possible cost, is the chief problem to be solved in church building, would be a great achievement. Something has already been done towards this very desirable end, and the work is progressing. The fact once thoroughly understood, that more worshippers may be seated by means of open benches than in pews, will in this utilitarian age, operate more powerfully in leading to their disuse, than any of the other numerous arguments against them which have been advanced. So far as appearance is concerned, there cannot be two opinions on the subject.

As an artist and an enthusiastic, though humble, advocate of the fine arts, the writer cannot regard the present views on church decoration, but with gratification, seeing in them the promise of a noble field for their exercise and development. Less than seventy years ago, Sir Joshua Reynolds, West, Barry, Dance, Cipriani, and Angelica Kauffman, offered munificently to adorn the interior of St. Paul's Cathedral with paintings, with the view of convincing the public of the improvement in our sacred buildings, which might be effected by this means, and so of obtaining an opening for the encouragement of British art. The then Archbishop of Canterbury and the Bishop of London, however, could not be induced to entertain the proposition, on the ground that it savoured of Popery, and the idea was in consequence abandoned. How doubtful of one's own judgment should such marked changes in opinion make us—how tolerant of the sentiments of others should we be, remembering as all must, the different light in which we ourselves have viewed the same circumstances at different epochs, and the alteration which is constantly taking place in our own views and opinions.

In one of the latest publications of the Cambridge Camden Society, containing many very excellent suggestions,[3] it is remarked, "a church is not as it should be till every window is filled with stained glass, till every inch of floor is covered with encaustic tiles, till there is a rood-screen (?) glowing with the brightest tints and with gold; nay, if we would arrive at perfection, the roof and walls must be painted and frescoed." In carrying out such views it is hardly necessary to say, the greatest care must be taken to prevent a theatrical effect likely to result from such a course, unless pursued with great judgment. We

[3] "Church Enlargement and Church Arrangement."

are disposed to think a more moderate use of colours than has been made in recent restorations in London and Paris, might produce a result equally excellent in an artistical, and more so in a devotional, point of view. Scripture sentences upon the walls, "ywritten full thicke," are amongst the most excellent and fitting adornments of a church.

The increased use made of stained glass in England is exceedingly gratifying, and the excellent specimens which have been prepared lately show clearly, as the writer has on many other occasions asserted, that we could produce stained glass quite equal to anything that was done by our forefathers if proper encouragement were afforded to the professors of the art. Difficult of attainment, expensive in its processes, so much so, indeed, as almost to prevent experimentalizing except for actual commissions, and labouring under the weight of an erroneous opinion that the art was lost, glass-painting had remained for a long time in a very languishing condition. Latterly, however, it has revived considerably, and many large works in various parts of the country are now in progress. The opinion entertained of our want of skill in glass-painting is hardly yet removed. The author of "A few words to Church Builders," says, "stained glass is of much importance in giving a chastened and solemn effect to a church. Those who travel on the Continent might find many opportunities of procuring from desecrated churches, at a very trifling expense, many fragments which would be superior to any we can now make. But if it be modern, let us at least imitate the designs, if we cannot attain to the richness of hues which our ancestors possessed." Against the opinion to be inferred from this, we will venture to place our feeble protest. There is much old stained glass to be found on the Continent inferior to what we can now make, and there is not a great deal which we could not equal if the proper opportunity were afforded. Moreover, we do not believe there are any hues possessed by our forefathers which could not now be produced.

Let every material employed in the construction of a church be *real*, is a wholesome injunction likely to produce excellent results, although, perhaps, some may think it could be carried too far. It has been too much the custom to endeavour to produce a showy and deceptive external appearance, without proper regard to the fitness, propriety, and excellence of all the various parts of the building, which, indeed, have been sacrificed for it. While deal painted to imitate oak, and Roman cement in lieu of stone, give entire satisfaction to ourselves, and obtain the approval of the world, no efforts will be made to obtain that which is better, and a niggardly calculating spirit is engendered, grudgingly giving the "just enough," which is unworthy of Christians, and destructive of more good feelings than one.

In *designing* buildings in the pointed style, this same doctrine cannot be too constantly reflected on. The more fully our ancient edifices are studied, the more clearly does it become apparent that nothing was introduced unnecessarily or deceptively for mere appearance sake—that the excellence of effect, which is apparent, resulted from the use of sound principles, laid down not with the view of producing that effect, but with reference to stability, convenience, and fitness; good taste and great skill being afterwards employed in adorning that which was necessary, and making the Useful a producer of the Beautiful. Plans were not made to accord with a fanciful elevation, entailing thereby loss of convenience, and unnecessary outlay, but were arranged first, to suit the requirements of the time, and upon these naturally the elevation followed. All decoration grew out of the construction, and reason governed instead of caprice. This is now better understood than it was a few years ago, and will doubtless produce its fruit in due season.

The virtual abrogation of the regulation, at one time enforced by the "Incorporated Society for Building Churches," that no timber roof should be used without a tie beam, will do much to restore to modern churches one of the most striking features of ancient buildings—the open arched roof—and is a subject for congratulation. The same may be said of the feeling now fortunately growing, against the tasteless tombs and monumental slabs with which our noble cathedrals and churches have been gradually encumbered and overladen. Like some frightful fungus, they have spread insidiously over all parts of these structures, destroying alike their beauty, propriety, and stability. Our metropolitan Abbey presents a lamentable example of the evil; and it is to be hoped that the acknowledged good taste of those who now govern there, will not merely prevent the increase of this abomination, but lead, as opportunities may from time to time offer themselves, to the removal of the excrescences now deforming that fine building, and to a restoration of its harmonious proportions and original integrity.

To say that every one of our ancient buildings should be most religiously preserved, is perhaps, less necessary now than it was some little time ago; still it cannot be repeated too often, for alas! instances of injury and destruction still occur, and not unfrequently. Full of information, abundant of association, and suggestive of most wholesome thoughts, they are contemporary histories, which once lost, can never be replaced; and in which every alteration even, or interpolation, is an offence against society. They are the visible links which make the past and the present one; they are the standing monuments of the Christian religion, and attest at one and the same time our forefathers' piety and our forefathers' skill.

THE NEW ROYAL EXCHANGE.

Instead of being at all premature, some of the remarks we are about to make come too late to be of the service they otherwise might—that is, supposing suggestions so thrown out to be ever attended to, which may fairly be questioned; for although architects are apt to be not a little sensitive when their productions are animadverted upon, they rarely seem disposed to screen themselves from criticism by attending to, and profiting by, what it has objected to, either in their own works or those of others. It is probable, therefore, that our observations will be of just as much service now, as they would have been if brought forward when they could have been acted upon, at least fully taken into consideration before it had been determined to pursue an opposite course. But with regard to consideration, none at all, as far as we can ascertain, appears to have been given to what was one of the most essential points to be deliberated upon at the very outset, viz. whether the new Exchange should be covered in or not. All we know is that, instead of its being made a question, it seems to have been settled, or rather assumed as matter of course, that it should be a mere open court, such having been the case in the former building. No idea of the possibility of any thing else appears to have occurred to any one—at least not to any one who had a voice in the matter. Yet though we say it should have been made a question for discussion, we do not think there was occasion for much discussion, the advantages of the central area being covered in instead of left open, being so many and so obvious, that merely to specify them would have been sufficient, we think, to carry the decision at once in favour of such plan. What could have been urged in behalf of the contrary mode, the one actually adopted, we cannot even conjecture; therefore, if any arguments at all were adduced in its support or justification, we should be exceedingly glad to learn what they were—which is more, we suspect, than any one can inform us. The only satisfaction then left us, until we are so informed, is the liberty of concluding that, notwithstanding all that was said at the time about the vast importance of the Royal Exchange as "a National Edifice, that should be in every respect worthy of the first commercial city in the world," and much more to the same effect: very little of careful consideration seems to have been bestowed upon it, great as was the delay, and noisy as was the squabbling as to who should be the architect.

Had a thought been given to the matter at the outset, it would probably have been perceived that, even supposing it otherwise mere matter of indifference whether the area were covered in or not, there was a golden argument to turn the scale in favour of its being covered —namely increased rental from the shops on the exterior of the building, in consequence of the greater space that could then have been given up to them, without at all interfering with the accommodation required for the body of the Exchange. According to Mr. Tite's plan, the entire space occupied by the latter will be about 19,000 square feet, but out of this number, 6500 will be quite open and unsheltered, consequently cannot always be made use of for purposes of business. Now had it been determined that the centre portion of the plan should be covered in, there would have been shelter every where, therefore the breadth of the ambulatories might have been considerably reduced, so as to afford an additional depth of nine or ten feet to the shops—some of which will now not be more than 7 feet in depth, or hardly that. Even then the actual space available at all times for business would have been the same, or rather more than will now be the case. And so far from the architectural effect being at all injured by such contraction of the space behind the columns, it would, in our opinion, be improved, and the whole would, in fact, appear to be more spacious than it is now likely to do; for the width of the cloister portion or ambulatories will now be so great, in order to provide a sufficiency of sheltered space, that while they will look low and depressed, they will occasion the open part or court to appear comparatively narrow and squeezed up; more especially as the same space looks considerably less when uncovered than when roofed in.

We have heard it urged as an objection to the Exchange being covered in, that it would be exceedingly difficult to light it from above without a very great sacrifice of architectural character. We, ourselves, however, are of a diametrically contrary opinion. Even supposing it to be covered by a mere skylight as a protection from the weather (as is the case with the cortile of the new structure at Liverpool, called the Brunswick Buildings) we do not see how that could interfere with the architectural elevations of the sides. We do not say it would be an improvement in point of appearance, but it would not be any great drawback on it. Hardly, however, should we recommend a skylight of that homely description for such a place as the Exchange; and skylights admit of being put into such a great variety of form, whether introduced so as to appear mere cofferings or panels receding little within the general surface of the ceiling; or as lanterns,—which may be ceiled above, and open only on their sides; and further admit of such great diversity of decoration, that a roof of the kind may be accommodated to any style and any design. While it is the most original, its ceiling, with three large skylights of plate glass (each consisting of two sloping planes parallel with those of the external and internal roof), is not the least happy idea in the interior of the Walhalla, and certainly magnificent enough, it consisting almost entirely of bronze and gilding.

For these fifty years at least, not a single edifice has been erected for the purpose of an Exchange for merchants either in Europe or America, but what has been covered in and protected from the weather, and now, instead of further improvement being aimed at, we are reverting to the old inconvenient plan of a mere open court, and to what, as such, will be no better than a pent-up and dismal area, except, perhaps, during a few remarkably bright days in the course of a summer. Almost might it be imagined that the "open court" had been determined upon, by the company of umbrella-makers, and by that of "undertakers" also. The city worthies seem to have either a very singular taste for uncomfortableness, or else very singular notions of convenience. No sooner had the public began to congratulate themselves on the very great advantages attending wooden pavements, than Sir Peter Laurie set about attempting not to *put them down*, but to take them all *up* again.

The architect of the Royal Exchange has, it seems, had sufficient influence with the Committee to prevail on them to have the pediment of the portico enriched with sculpture; let him then now recommend, while it may be yet time, that the "area" should be covered in above, for then it would be protected from the atmosphere and its London smoke, as well as from the weather; and as a hall it would not only appear more spacious than as an open court, but also more lightsome and cheerful—certainly would be more cleanly, because its pavement would be always dry.

As to the difference of appearance in regard to spaciousness, there can be no doubt; for what sort of effect, we ask, as to size, would Westminster Hall make without its roof. To an open cortile, in itself, there can be no objection; but, we must contend, it is preposterous to adopt it for a purpose where something more is obviously required.

CANDIDUS'S NOTE-BOOK.
FASCICULUS XLVI.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. Since Mr. Gwilt not only entertains, but professes, so great a horror of architectural critics, anonymous writers, amateurs, and "literary idlers," as it pleases him to call them who amuse themselves with architectural studies, it is to be hoped that some of them will horrify him yet more. Myself, for one, it may be presumed, am numbered by him among the most offensive of the tribe, and reckoned an incorrigible *mauvais sujet*, and mischief-maker. Nothing, however, can be more mischievous, or more completely opposed to the interests of architecture, than the doctrine he puts forth; for the drift of it is not to encourage the study of it as an art, but actually to *deter from* it. He would confine it entirely to the profession, treating with scorn the idea that any one else can acquire a competent knowledge of it, even as a fine art, or form a correct taste. In his opinion, the less the public know, or pretend to know, of it the better; and if he means better for himself and those (if there be any) of his way of thinking, he is undoubtedly right. Hitherto it has generally been made a subject of pride and congratulation, that architecture has enlisted among its most zealous votaries, persons of refined taste and liberal education, many of whom have rendered it essential services by their pen. But Mr. Gwilt views the matter in a very different light: he is for changing it altogether, and "*heretoforward*"—to make use of his own quaint expression—the whole race of Benthams, Hopes, Dallaways, Whewells, &c., are to be looked upon as mere "literary idlers," who, furnished with no more than a few purblind ideas, and crude notions, which they have picked up by chance, pretend to instruct and inform others in matters of architecture. Yet it is to such industrious "idlers," that we are indebted for the far greater part of what is known of the history of the art; very little information of that kind has been supplied by architects themselves, and what they have written at all seldom extends further than to the mere elements and dry rules of their art; what may be termed the philosophy of it, being rarely touched upon by them.

II. Instead of taking it amiss of Gwilt that he has omitted his work in his list of architectural publications, Wightwick ought to consider himself a very lucky fellow in escaping a good dressing from him, for having recommended the study of architecture as a very delightful, and also a very suitable, one, not only for "idle" gentlemen, but *proh pudor!* for "woman kind" also. He and Gwilt are the two poles of opinion; while the latter would confine the study to those whose proper *business* it is, Wightwick would have it rendered accessible to all; the one would have it kept as a well-watched *preserve*, with a due warning of "Man-traps and spring-guns" to scare away the public—the other is for breaking down all its paling and fences, and throwing it open as a *common*, where every one may stroll, and where literary *geese* are free to pick up what they can, and to hiss, without having their necks wrung off for their presumption. It is Gwilt's opinion that the less the public meddle with architecture the better; on the other hand, Wightwick's, that the more the public understand and render themselves competent judges of it, the better both for them and for the art itself, and those who practise it. Nor is it altogether unreasonable to suppose that people would take more interest in what they understood, than in what they are now ignorant of; and further, that the greater and more extended the interest taken in it by the public, all the better would it be for those whose interest of another kind it is, that, instead of a mere swinish multitude, they should have an intelligent public to deal with. As far as there is cause for complaint in that respect at all, it is not that there are so *many* "amateurs" and persons without the pale of the profession who study, or pretend to study, architecture, but that there are so *few*. Infinitely better would it be if the whole public, that is all persons of education were in a manner amateurs.

III. At last Boz has introduced a new character—one which has hitherto not been handled by either dramatist or novelist—in the person of Mr. Pecksniff, the architect. All other professions—the medical and the legal more especially, have been represented and shown up so frequently, that characters of that class are almost worn out. The wonder, therefore, is that no one should have before thought of turning to the architectural one. Whether, in entering upon this fresh track, Mr. Dickens has provided himself with a *carte du pays*, remains to be seen, for all that can be understood at present is, that Pecksniff is to be a very prominent character in the work; but it is not quite so clear if he is intended to be the representative of a class in the profession, or merely an individual who might equally well have been represented as belonging to any other. If, as he very well may do, Boz should show up the peculiar kind of charlatanry which stamps the architectural quack, and distinguishes him from all others of the duck-like genus—should he expose the arts by which men totally destitute of artistical talent and feeling for *art*, obtain credit with the public for being artists—should he disclose some of the clever tricks practised at competitions by very "respectable" people—should he indulge in some pleasant hits at the *vox et præterea nihil* pedants, who can merely talk by book and by rote, without an idea of their own—should he, among other things, exhibit Pecksniff as an architectural lecturer, gammoning his bewildered audiences with mere rhodomontade and fiction,—should he do this, Dickens will deserve our thanks, and the gratitude of the honest part of the profession. Still we have our misgivings, and suspect that Pecksniff will turn out rather an overdrawn and ill-drawn caricature, than an ably delineated character, and portraiture from real life. Of extravagant and tedious caricature there is certainly not a little, in the manner in which Pecksniff is first presented to us—blown down by the wind at his own door. Had any one else given us such a tirade of laboured nothingness, and dull attempt at grotesque pleasantry, it would at once have been pronounced intolerably childish stuff; whereas, now the critics will perhaps discover it to be very fine—one, indeed, has done so already.

IV. I entertain about the same affection for law books that Gwilt does for German architecture and German architects. Why does not a second Omar come to purge the world of them? Even a book bound in "law fashion" has to me a very odious look; it seems to have put on the uniform of that Tartuffe race of wolves in sheep's clothing, or at any rate wolves dressed up in calf's skin. Nevertheless, I have done that which a month ago I should have said was impossible; yes, I have actually been seduced into reading an article in the Law Magazine, one, certainly, that I should never have thought of looking for there, consequently might never have known of at all, had it not been put into my hands by a friend, when, to my utter astonishment, I found it contained a paper headed "*Architectural Novelties*"! It was like having a sovereign *palmed upon* one between a couple of halfpence; almost was it like my first meeting with Young's descriptions of magnificent country seats, sparkling like bright and verdant oases over the arid waste of such dreary matter as crops, and hoeing and drilling. Most truly does the poet say:

> "Full many a gem of purest ray serene,
> The dark unfathomed caves of ocean bear."

yet I doubt if the dark unfathomed caves, or bottomless pit of the law, contain anything more relating to architecture, whether in the shape of "novelties" or antiquities. There can, however, be no doubt, that a vast number of papers, of one kind or another, relating to architecture lie buried in literary journals and periodicals, foreign ones more especially. Were the best, or even some of the most interesting of them, collected and reprinted, they would form a *Reading* Architectural Library of considerable extent. It is by poking about in periodicals that we stumble upon such treasures as Edward Collow's descriptions of, and remarks on, many of the recent public buildings of Paris—things, therefore not likely to be met with by gentlemen like Gwilt, who despises periodical literature, and, though he has not ventured to say so, no doubt abhors architectural periodicals most of all. Neither are they likely to come to the notice of those who pore over the writings of the "venerable" Vitruvius, and carefully collate all the readings of different authors, in hopes of being able to catch a glimpse of the meaning of the mysterious "*Scamilli impares.*" But the Law Magazine;—be it known, then, to all whom it may concern, that its article on "Architectural Novelties" gives some account of the Hall and Library about to be erected by Mr. Hardwick, in the gardens at Lincoln's Inn, at the south-west corner or south end of the terrace. The building is to be of red brick, and in the style of the older parts of Hampton Court. The Hall or Dining Room will be 120 × 15 and 54 feet high, and the Library 89 × 40 and 48 feet high; and both will have timber roofs. The remainder and longer part of the article relates to the restorations and embellishments of the Temple Church.

V. Raczynski is pleased to speak in exceedingly complimentary terms of the architecture of Edinburgh, and its recent buildings, as being in better taste than those of London; but then it is only in such safe general terms, that what he says amounts to nothing—at least to nothing more than a bare opinion to that effect, for he does not even mention a single one of the structures he pretends to admire. If the Nelson Monument was one of them, his praise is not greatly to be coveted. Speaking of that "monstrosity," the writer of the "Remarks on the Edinburgh Parthenon," tells us that "it ought to be pulled down"; nor is the same unlikely to be said of the other "Nelson Monument" in Trafalgar Square.

VI. It is provoking to find that the stupid Germans now propose to erect a public monument to Schinkel, just after Gwilt has put an extinguisher upon him. A public monument to a fellow who was no more than a mere "scene painter" in architecture! to one who was little better than an audacious heretic in the art, an insolent reformer, setting at defiance both Pope Vitruvius and Pope Palladio, and did not even abide by the authority of the Greeks themselves, but would fain be "*tampering*" with the ancient orders, like a conceited coxcomb as he was, in the hope of improving them, or at least of producing something as good, and not quite so hackneyed. A monument to Schinkel, indeed! Zounds! we will be revenged on those scurvy Germans, for we will erect a public monument to Gwilt; therefore the sooner he gives us the opportunity of doing so, the better.

PONT DU CARROUSEL, PARIS.

In the *Journal* of August, 1842, I stated that an improvement worthy of notice had been introduced in the construction of the Pont du Carrousel, at Paris, consisting in the application of wrought iron keys, so disposed as to obtain great precision in setting the segments of the tubular voussoirs, of which the arches of this bridge are composed. My intention is to explain more particularly in this paper, how far the application of these keys materially facilitated the casting of the voussoirs separately, and to show their useful effect in the construction of the arc on the piers.

The amount of contraction of cast iron, in the act of cooling in the mould in which it has been run, is variable; for although, as stated, the general average may be considered to be about $\frac{1}{100}$, this measure cannot be taken as an absolute quantity: it may be sensibly modified, by many circumstances, such as the quality of the metal, its temperature when run into the mould, and the greater or less rapidity of the cooling process. This difference is not of material importance in short pieces, but in a length of upwards of 160 feet, it may amount to some inches, and when the pieces are cast in great lengths, (or even if they are in short lengths,) and the joints are intended to bed fairly against each other, as is the case in bridges of the ordinary construction, this difference becomes a source of considerable trouble and annoyance.

It is objectionable to have to add to the length of pieces when cast, and to avoid this, the patterns are usually made full long, thereby allowing for the greatest possible contraction of the metal; so that generally speaking, a certain portion of each casting has to be removed by the chisel or otherwise, to get the pieces to their proper length. Notwithstanding these precautions, there will be occasional wasters, which may be properly or improperly patched up, or which if thrown away, give rise to extra expense and delay.

When the constructor has plenty of time at his disposal, he proceeds with still further caution, by casting the principal pieces, and having them put together; after this, the pattern of the remaining length is corrected, and sent to the foundry with the certitude, that the casting will come in pretty well; thus, by dint of precaution, delay, and expense, the work is got through to this stage, and if the mason work is prepared with the same care and precision, all will be found to come in very well; but a stone pier has been known to be a little out of its proper position, either in consequence of an error or the settling of the work upon its foundation. When this takes place, it becomes requisite to let the cast iron into the stone work on one side of the pier, and to place a thickness of metal between the pier and the cast iron on its other side. All these imperfections are only felt during the construction, they do not at all diminish the strength or interfere with the durability of the work, but generally speaking, all those who have been engaged in cast iron bridge building, will have had to exercise their ingenuity, not only to correct such evils, but at the same time to proceed in such a manner, that they may not leave an indelible trace on the face of the work. There is, therefore, no doubt but that the facility of extending, or diminishing, the chord line or the versed sine of the arch, would on many occasions be of considerable advantage.

The keys placed at each end of the segments, of the tubular voussoir, remove all the above mentioned objections, for the segments being kept rather short, the space will have to be divided amongst some 10 or 12 joints, so that three or four inches, more or less, in the total length of the arch, will only require the wrought iron keys to be made a little thicker or thinner than they were originally intended to be, and as they are not made until after the arc has been placed, no extra expense will be incurred, or time lost.

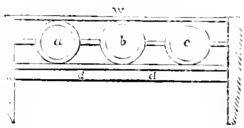
The division of the arc into so many pieces, offers another advantage, as, by reducing the weight of each separate piece, the whole can be moved about, and managed with great facility, and without requiring such powerful tackle, or such strong centering, as is generally employed. When the number of segments comprised in an arc are in their place, a wood model is made for each key, and the keys are forged and fitted in their places, without being immediately driven home; plumb bobs being suspended from the joint of the tubular rib, it becomes very easy to set the whole in a perfect line, by driving the keys on either side as may be required; and by making the keys sufficiently long, the height of the arc can be regulated with the utmost facility and precision. The keys being driven, and the whole of the tubular arc in its proper place, the bolt holes, those of one flanch having been cast in, are drilled in the opposite one, and the bolts placed and tightly screwed up, attention being paid at the same time to the plumb bobs, as the effect of screwing up the nuts may be to cause a deviation in the line of the arc, which is again easily rectified by means of the keys, and the bolts cannot otherwise affect the form of the arc.

Openings were reserved from distance to distance along the upper joint of the voussoir, for the purpose of introducing melted bitumen, which, when the bridge was finished, was done, in order to fill up the space remaining between the lamellated wooden rib, and its cast iron covering. This bitumen being intended, by setting when cool, to form a compact mass of the whole arc, with a view to increase its rigidity.

The wooden arc, as I have already said, greatly facilitated the erection of the tubular voussoir, and when standing alone, previous to the application of the latter, it had a wonderfully light and elegant appearance; but it becomes a question whether, in reality, it is at all requisite to the solidity of this kind of bridge, its flexibility being so great that it cannot in any way be expected to come to the assistance of the cast iron, which, if accidentally forced out of its original position, by any extraordinary lateral strain (the only one that could affect it) would break long before the internal wooden rib could offer any useful resistance to the strain. It also remains to be ascertained whether the wood thus confined in the tubular voussoir, will not be very subject to decay, notwithstanding every precaution that has been taken to preserve it.

The annular system of spandrils, adopted by M. Polonceau, forms another remarkable feature in this construction; they combine strength with lightness, and give an elegant appearance to the bridge. Their circular form renders them elastic; they spring under the load, so that the vibratory action, communicated to the roadway, and the upper side of the annular support, is neutralized ere it can arrive at the main rib, which, therefore, as I have already observed, maintains the most rigid firmness, under the heaviest load.

At the same time that the vibratory action is destroyed, they present also the advantage of distributing the load acting at a particular point on the road, over a considerable length of the main rib of the arch, as will be shown by the diagram.



Let us suppose three rings *a*, *b*, *c*, placed between a beam *d*, and an upper platform; and that a weight W be placed on the platform immediately over the ring *b*; under such circumstances the vertical diameter of the ring *b*, will be shortened, and its horizontal diameter will be lengthened in the same ratio; half the increased length of the horizontal diameter of *b*, will be taken from each of the horizontal diameters of *a* and *c*, and added to their vertical diameters, thus raising the platform immediately over the centres *a* and *c*, and by increasing its resistance, will remove a portion of the load W from the point *b*, to the centres *a* and *c*, thereby distributing it along the beam *d*.

As a proof of the advantage of this mode of construction in point of economy, it will be sufficient to mention, that although the length of this bridge between the buttresses, is nearly 500 feet, it was completed for £40,000, including every expenditure; and that, in a country where metal is very high priced. I can conscientiously affirm, that every precaution was taken, and every outlay made, that could be required to obtain good workmanship, and a solid construction. The whole of the tubular ribs were moulded in dry sand, and cast in second fusion, and the wrought iron employed is of the very best quality for the purpose.

When the bridge was finished, it became necessary, according to the government regulation, to test its strength by distributing a given load over the entire surface of the road way, the government officers in the meanwhile, minutely inspecting the work, to ascertain whether, under the strain, any defect would become apparent. This, in France, is an invariable rule adopted as a legislative measure of public security; and, until you can present a favourable report from these officers, it is impossible to obtain permission to open the bridge. We commenced by making an observation in the morning early, to determine the positive height of each arch, previous to any load having been placed on the bridge. The load (about 400 lbs. avoirdupois upon every square yard of surface) was then laid on, and in the afternoon we found that, under the load, each arch stood higher than it did in the morning without the load.

The morning (October) had been very cool, the sun coming out later in the day heated the metal, and increased its length, so that the whole difference in the height was occasioned by expansion; it became, however, requisite to ascertain if such was positively the case, and by leaving the load on the bridge, and taking an observation again when the metal was cool, we found that the arches had returned to their original position. There is nothing surprising in this circumstance, although without reflection it would appear rather paradoxical, and I mention it, not with a view of exemplifying the effect of expansion, which is of course understood, but because I consider the peculiar system on which this bridge is constructed, to be favourable to the free action of expansion and contraction, without thereby being subjected to any strain at all detrimental to its general strength.

The part of the bridge, most immediately exposed to the action of heat and cold, and more particularly to the action of the sun, is the arc itself, the upper part of the spandrils being protected by the projection of the platform, consequently large castings would be subject to unequal contraction and expansion and consequent strain, which must very much weaken them, whereas, in bridges constructed upon this principle, the flexibility of the whole system is so great, that the expansion of the tubular rib, by increasing the versed sine of the arc, can lift the entire arch without subjecting any part of it to such a resistance as would tend to diminish its strength.

H. H. Edwards.

London, Feb. 20, 1843.

VARIABLE ORIFICE OF THE BLAST PIPE OF LOCOMOTIVE ENGINES.

In the February number of the *Journal*, I described a "*Self-acting Expansion Slide Valve*," and in the course of the explanation, referred to having obtained patents abroad for an apparatus, by means of which, the orifice of the blast pipe of locomotives, can be regulated by the engine driver; I will endeavour in this paper to describe the apparatus, and to point out its general utility.

The determination of the area of the orifice of the blast pipe, is of importance in the construction of locomotives; upon its proportion depends the supply of a sufficient quantity of steam for the service of the engine, and also its comparative effective pressure upon the piston. It may be made so large, or so small, as to prevent the engine from performing her allotted amount of duty; and the application of this blast of steam, may be considered (next only to the boiler itself), the most useful invention in this beautiful machine, so essential a complement thereto, that the locomotive engine would have been very imperfect without it. The possibility of its successful application having been ascertained, experience promptly indicated the extreme limits of the area of the blast, within which the engine could exert her power; but it still remains to be decided as an invariable rule, what the exact size should be within these limits, to produce the most useful effect; and you will very seldom find any two engineers who adopt the same sized blast, for engines of the same power.

When the diameter of the orifice of the blast pipe is too great, the energy of the blast will decrease, and the draught through the fire will not suffice to generate the quantity of steam required to keep up the speed of the engine; when, on the contrary, the diameter is too small, the resistance behind the piston will become so great, in consequence of the steam not being able to escape through the contracted passage, as sensibly to reduce its effective power on the piston. Within these two extreme limits (if an invariable orifice of blast is adopted) it at first sight appears, that there must be an intermediate point at which, if it could be attained, an engine would perform the greatest quantity of work, with the smallest quantity of fuel. This intermediate point, if it can be admitted to exist, is exceedingly difficult to discover, because a locomotive engine has to overcome a degree of resistance that is constantly changing, either on account of the load, the action of the wind, the state of the rails, or other causes.

In the preceding paragraph, speaking of the extreme limits of the size of blast, within which an engine may work equally well, some doubt is expressed as to whether there exists an intermediate point that might be preferable, as enabling the engine to perform more effective duty. It is probable that within a certain limit, the blast (if invariable) may be made of any intermediate size, without sensibly influencing the average effect produced, the inconvenience and advantage resulting from the change being so nicely balanced, that no sensible difference could be discovered. If such is allowed to be the case, the efficacy of the variable blast must be manifest without a trial.

In order to diminish the resistance behind the piston at the return of the stroke, the elasticity of the steam has been taken advantage of; a chamber placed at the foot of the blast pipe, by allowing the steam to expand on its escape from the cylinder, relieves the engine, and has permitted the adoption of the most contracted orifice of blast, that I have yet seen successfully employed. The greatest relief, however, has been obtained by throwing off the steam considerably before the piston arrives at the end of the stroke, thereby enabling it to expand before the return of the piston, and thus very effectually diminishing its resistance; and although by so doing a portion of the effective power of the steam is lost, it is at the same time a judicious choice between two evils, and if not adopted, the discharge of the steam from the cylinder at the moment of the return of the piston would determine a powerful resistance to its free action, and so reduce the effective power of the engine.

The contraction of the blast pipe being an inconvenience inseparable from the condition of generating a good supply of steam in the locomotive boiler, it becomes important to partially remove this inconvenience when practicable; and as the state of the fire, and the quantity of steam required, are frequently varying, it may be positively assumed that an invariable contraction of the blast pipe is an imperfection, and that even supposing the question as to the best possible dimension were decided, and a generally admitted rule laid down, it would only then be really perfect for some particular load, and state of the fire; and that with a different load, or state of the fire, the determined orifice of the blast would be objectionable; therefore, it may be concluded that the faculty of regulating the contraction of the blast, so as to have full power over the production of steam, must be in itself a desirable condition, and that if by the same means, the average resistance behind the piston can be diminished, the "ensemble" may be admitted to be a material improvement.

It frequently occurs that there is either too much, or not enough steam in the boiler; when there is too much, it is the usual custom to open partially, and sometimes entirely, the fire door, so that by admitting a current of cold air into the fire box, and through the tubes the production of steam will be diminished; but this remedy is very objectionable, and should be applied as seldom as possible, because the rush of cold air may give rise immediately, or subsequently, to leakage in the hoops, and must very much contribute to the destruction of the tubes, and to injure the boiler itself; whereas, if it were possible to enlarge the orifice of the blast pipe on such occasions, the fire would be damped, and the steam would fall, probably without having to open the fire door at all.

When there is not enough steam, the draught through the fire, in consequence of the low pressure of the steam, and the slow motion of the engine, will necessarily be less energetic than it ought to be, the means of exciting the fire becoming inefficient at the time when its assistance is most wanted. A good engineer will certainly take care that this occurs as seldom as possible, but there are accidental causes over which he has not sufficient controul, and on such occasions the power of contracting the orifice of the blast pipe would be very beneficial, by enabling him materially to increase the rapidity with which the fire would be brought up to its proper state.

When a heavy train is going up a steep incline, its speed will decrease; the strokes of the engine being less frequent, the draught through the fire will also diminish in intensity, and the quantity of steam generated may no longer be sufficient; a slight contraction of the orifice of the blast pipe would then increase the power of the blast, the action of the fire, the production of steam, and the speed of the engine.

The engine driver generally manages his engine and fire, in such a manner, as to obtain a full supply of steam previous to his arrival at the foot of the incline; with the assistance of the variable blast, he would naturally (having plenty of steam) enlarge the orifice of the blast pipe, and thus by diminishing the resistance behind the piston, would increase the power of the engine, so that although going up the incline, she might still maintain sufficient speed to keep up the steam, notwithstanding the enlarged orifice of the blast pipe.

When running down an incline, the orifice of the blast pipe being opened to its greatest extent, the draught will be considerably diminished, because at the same time the regulator will be partially shut; the steam may in this way be very effectually kept down, although the incline may be many miles in length: and by contracting the orifice towards the approach of the foot of the incline, steam may be again obtained, without having had to expend steam from the boiler, to increase the draught through the fire, thus effecting an economy in the consumption of fuel.

By good management, the engineer can therefore have full power over the production of steam, so as at all times to have a good supply, and to prevent almost entirely the loss occasioned by its escape from the safety valves while the engine is in motion; and taking into consideration the frequent occasions on which advantage may be derived by varying the orifice of the blast pipe, it may be inferred that it is as requisite to have full command of this orifice, as it is, to be able to determine the position of the regulator. The speed of the engine may, moreover, be occasionally regulated with advantage, by varying the orifice of the blast pipe, without altering the position of the steam regulator.

To carry out, in a practical manner, the variable contraction of this orifice, it is requisite

That the apparatus should be easily constructed and applied, and not liable to get out of order;

That its action should be simple and effective;

That an indicator should show the area of the orifice under which the engine is working.

Having pointed out the general advantages I propose to derive from the application of a variable blast, I will now describe the apparatus that has been employed, which will be clearly understood, with the assistance of the annexed figures.

In the construction of this variable blast, there is one point on which it is proper here to make a remark, which if not attended to, would materially tend to destroy the good effect to be produced.

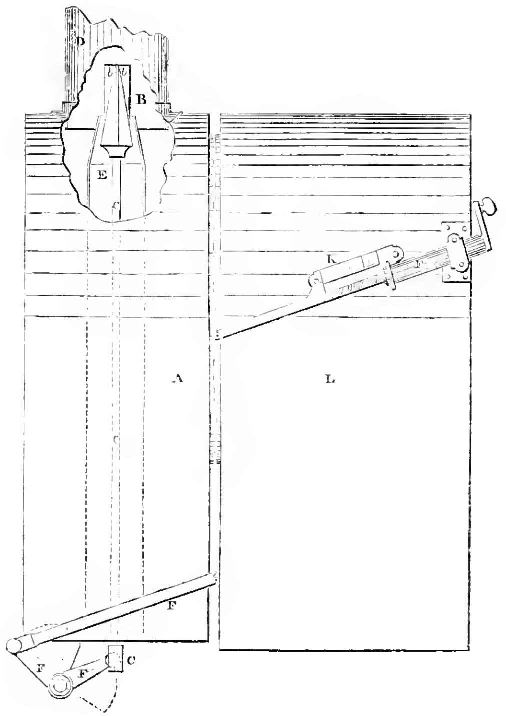
The annular space between the internal cone and the orifice of the blast pipe, if too much contracted, diminishes the energy of the blast; so that it is necessary that, at the point of greatest contraction, with a view to obtain the strongest draught, the relative diameter should be so calculated as to leave nearly a half of an inch of space, for the passage of the steam between the internal moveable cone and the edge of the blast pipe.

The intensity of the draught through the fire can be weakened, therefore, either by enlarging or by contracting the orifice of the blast pipe, beyond a certain limit. I have occasionally regulated the motion of an engine by the contraction of the blast pipe, leaving at the same time the regulator wide open, because by contracting the orifice more or less, the pressure behind the piston may be varied, and so regulated as to augment or diminish the effective action of the steam on the piston. The adoption of this variable blast may also be considered as an extra security, for by keeping the internal regulating cone of the blast pipe closed, while an engine is required to remain stationary, no danger could arise from the accidental opening of the regulator.

Explanation of the Figures.

Fig. 1. Longitudinal elevation of a Locomotive Boiler, part of the smoke box being removed to show the extremity of the blast pipe. The circular portion of the boiler between A and L is omitted.

Fig. 1.



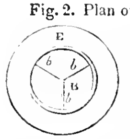


Fig. 2. Plan of the orifice of the blast pipe, showing the regulating internal cone B, with its three guide ribs *b*, *b*, *b*, upon an enlarged scale; A, smoke box; B, regulating cone of the variable blast; *b*, *b*, *b*, three thin ribs or feathers, attached to the regulating cone B, for the purpose of keeping the cone B exactly in the centre of the blast pipe; C, vertical rod, to which is attached the regulating cone; D, part of the chimney; E, blast pipe; F, hand gear to work the cone B; K, graduated plate fixed to the fire box, to show the position of the cone B, and the exact area of the orifice of the blast pipe; L, fire box.

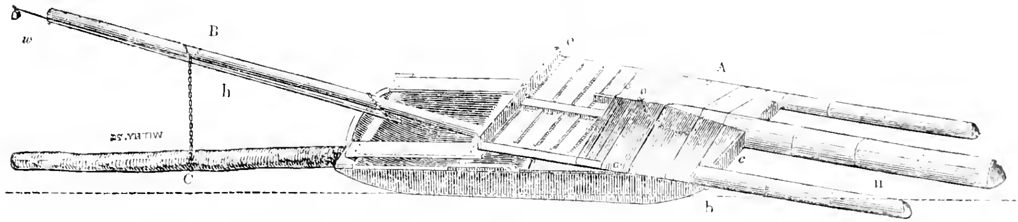
London, Feb. 11*th*, 1843. H. H. Edwards.

The Tomb of Napoleon.—The following details are given by one of the journals respecting the tomb in honour of Napoleon at the Invalides:—In the lower part of the equestrian statue of the Emperor, which is to be erected in the court-yard, a door will be opened to a long gallery leading under the dome of the building. This gallery, paved with marble in all its length, is to be divided into three sections—in the first of which will be placed bronze alto-relievos, representing the military deeds of the republic of the emperor. The second, which exists already, and is consecrated to the interment of the governors of the Invalides, is to be enlarged, and the tombs at each side will be fenced off with bronze railing. The third section will be also adorned with alto-relievos in bronze, recording the most notable acts of the empire not military. Under the dome will be placed the tomb of the Emperor made of Corsican granite. On it will be engraved, in letters of gold, the single word—Napoleon.

BALLARD'S ICE BOAT.



The above engraving is an isometrical view, drawn to a scale of eight feet to the inch, of the ice boat, for which Mr. S. Ballard, had the honour of receiving of the Institution of Civil Engineers a *Telford* medal.

This boat was first used in the year 1837, on the Hereford and Gloucester Canal, and has been in operation, whenever required, ever since. It breaks the ice by *ploughing* or *forcing it upwards*, and does not require more than one-fourth of the power necessary to break the ice on the old plan of forcing it downwards against the water.

The ice-breaking frame A consists of three pieces of timber marked *n*, fastened together by two cross pieces *c* and *e*. That part of the frame which lies over the boat is boarded or planked over; one part so as to form a platform for men to stand upon, the other part raised in the middle and cased with sheet iron, that the ice may not lodge on it. The frame lies on the front of the boat, which is sloped down as shown at *a b*. The frame is made with deal timber; the two outside pieces each 27 ft. 6 inches long by 9 in. by 5½ in. the middle timber 31 ft. long by 12 in. by 7 in. These timbers are rounded on the top as far as they project over the front of the boat, and the under sides are made narrower than the top sides.

The boat is decked over from *a* to *b*, and when the ice is very strong, she has a temporary boarding over, of inch board, as far as the centre. The spar B, which projects over the stern of the boat, has the large end chained down to the middle of the boat.

The piece of timber C is attached to the spar B by a chain. It is about one ton in weight, and prevents the boat rising behind when the ice presses upon the frame on the front of the boat. It floats on the water and the chain is strained in proportion to the thickness of the ice. The timber is also chained to the stem of the boat. By these means the slope or inclination of the ice-breaking frame is kept always the same, with the advantage of a short boat, which is easily steered and managed.

The pole or shaft *h* is for the purpose of steering the boat. It is attached to the end of the spar by a chain, and is balanced by a weight *w*, so that its weight may be trifling in the hands of the steerer who walks on the towing-path.

The boat, and also the upper sides of the ice-breaking frame are cased with sheet iron. The hauling line is attached to the chain *o*.

When the ice-breaking apparatus is not required, it may be taken off, and the boat used for other purposes.

THE GREAT BRITAIN STEAM SHIP.

It was but lately that our attention was drawn to an article, published in the *Nautical Magazine* for January last, written by Mr. J. S. Enys, entitled "Remarks on Nominal Horse-power," and which is evidently a critique on an article of ours published in the *Journal*, Vol. V. p. 357, on "The Great Britain Steam Ship," the same having been copied into the *Nautical Magazine* of last November.

The object of Mr. Enys's paper is to shew the fallacy of calculations made on nominal horse-power, in fact power calculated by the rules of the late Mr. Watt, in as much as modern practice has deviated from our great master in the amount of boiler pressures, from 2½ and 3 lb., to 5, 6, 7, 8, and sometimes 10 lb. per square inch, and then proceeds to prove that the consumption of fuel by the Great Britain will be just one-half or one-third (according to the expansion) of that computed by ourselves.—He states much that is true, and something that is erroneous, and we consider, that he is guilty of omission; inasmuch, that he does not follow out his argument (he is undoubtedly able) and demonstrate what diminution of speed would result on the employment of expansion, especially to so great an extent as *one-half* and two-thirds of the stroke.

We must do ourselves the justice to say, and we are sure our readers will agree with us, that our observations were temperate, written, not in a feeling of opposition, but merely to elucidate and draw attention to what we considered errors in practice. How far we are correct in our views with reference to the case of the *Great Britain* (late *Mammoth*) time and experience only will show, we are fully content to abide by the issue.

It will be seen on reference, that we expressly guarded ourselves against any misunderstanding with respect to the character of our data, and took the trouble to explain that we were indebted for them to Mr. Hill, a writer in the 996th Number of the *Mechanics' Magazine*, so that our deductions are dependent on the accuracy of the matter there given. It does not, however, appear that Mr. Enys disputes any portion excepting the correct delineation of the boiler details, so that we were right in taking the cylinder at 83 inches diameter, 6 feet stroke, and 19 strokes per minute. In our article we entered into a calculation, founded on the capacity of the cylinders and length of stroke (commonly called *nominal* horse-power, the only data at that time at our disposal), to prove that the consumption of coals, would, during a passage from Bristol to New York, be much greater than is supposed, or than they have allowed space for in the vessel. We are met by the scientific calculations of Mr. Enys, proving that by *expansion* to one half, or two-thirds of the stroke, the consumption of coal would be considerably reduced, in a much larger ratio than the power. It is, however, worthy of remark, that, although ourselves and Mr. Enys take different methods of computing power, that we agree in the amount of fuel which would be expended, supposing the engines to work to their full power, namely 129 to 130 tons per diem.

We have again carefully looked through Mr. Hill's paper, which confirms our impression that he did not state any *distinct rate of expansion* at which the engines were to be worked, he explains the construction of the expansion valves, which are not new; and as most modern engines of large powers are fitted with similar contrivances, we concluded that in this, as in other cases, the evaporative power of the boilers and strength of the materials were calculated to supply steam for, and to resist the action of, the full powers of the cylinders, expanding the steam only by the common sliding valve, *though refinements of the special expanding valves being used as in other ships, for the occurrence of fine weather and fair winds.*

Our justification on this head will be complete, when we state, that "The Great Western," Cunard's vessels, the "British Queen" and "President," were each fitted with separate expanding apparatus, but that their boilers are capable of generating a full supply of steam for an expansion of not more than ⅙th of the stroke—that is by the sliding valve, and it would be a matter of curious enquiry to see how frequently this is departed from. If our views be correct on this point, the general object of commanders of steam vessels, is to make the best of their way to their port without reference to the saving of fuel, *time*, in fact, being frequently of much greater value than a few tons of coals. We state this as a practical fact, for the saving of fuel by the expansion of steam is now well known to those who have devoted the slightest attention to the subject.

Nominal horse power is certainly but a conventional expression, designed by the late Mr. Watt, as an approximative measure of the commercial value of his engines, it was very applicable to the circumstances of his times, and perhaps, *until something better is produced*, as much so to ours. It is not, as it has been called, "empirical," because it is founded on rational grounds, *and if we could get all engineers to agree to one standard of computation*, it is doubtful if any better system could be introduced—it is a mechanical test from which no engineer can escape, and we are enabled, with the aid of the indicator, to apportion to its work just as much merit as it possesses: by its use we immediately discover the principles on which the engine is constructed, the rate of expansion, the state of the vacuum, the proportions and setting of the sliding valves, and other detail absolutely necessary to the good performance of an engine—in fact, we can distinguish between a good and a bad engine, between science and pretension—and in conjunction with data relative to the consumption of fuel can precisely compute the value of each man's work.

We say it will be difficult to produce anything better than this. The commercial world is satisfied, because they may be supposed to know more of a two foot rule, and its applicability to measure the diameter and length of a cylinder, than they can possibly be of the ratio, or of the rarefaction of water when converted into steam, or of the more intricate theory of expansion. No, the commercial man will continue to buy his steam engines by the capacity of their cylinders, and with the aid of his coal merchant's account, *and the amount of work done*, will come to a pretty fair conclusion, as to which engineer is most deserving of his confidence.

These observations have particular reference to marine engines, in which it is well known that *space occupied* and *weight* is of paramount importance, and it has been the aim of much consideration and reflection to obtain these, with the exertion of the greatest power at a minimum expence. We call this the *ne plus ultra* of marine engineering.

We may, therefore, doubt the judgement of the engineers of the *Great Britain*, who are using cylinders equal to 1200 horses, and by expansion, reducing the same to 700 horses, occupying both the weight and space of the former power; but perhaps we are again in fault, now reasoning on the *assumption* of Mr. Enys, as in the former paper on that of Mr. Hill.

Mr. Enys observes. "that nominal horse power is a most inaccurate basis for calculations of this nature," that is, the consumption of coal and speed of the *Great Britain*.

With reference to the first proposition, the consumption of fuel, we most freely assent. The value and the theory of expansion has been so fully explained by many writers, perhaps especially so by Farey, that it is beyond dispute—it is no new light which has burst upon us. A few years since, some attention was drawn to the published logs of certain steamers, in which assertions were made, that the consumption per horse was (as now reproduced by Mr. Enys,) as low as $6\frac{1}{2}$ lb. nominal H. P. per hour, and which was satisfactorily shewn to have been produced by expansion, during fine weather and favourable winds; but that, when the full power was exerted, the consumption of fuel reached from nine to 10 lb., the general result of the best machinery, so will it be with the *Great Britain*. If, as we had supposed, from the lucubrations of Mr. Hill, that her engines are designed, *when necessary*, to work to their full power, and by *full* power we mean expansion by the sliding valve alone, and exciting an average pressure on the piston of at least 14 lb. per square inch, exclusive of the friction, then will our computation of consumption at 10 lb. per horse be found correct; that is, supposing the engines and boilers, scientifically and practically constructed; but if any credit is to be attached to the delineations of Mr. Hill, we must be allowed to doubt if even this point of economy will be attained.

If it be intended to work these engines at a *permanent rate of expansion beyond that of the ordinary sliding valve*, a corresponding saving will accrue in the exact proportion of the length of the stroke worked by the dense steam; or, in other words, the quantity of steam used or admitted into the cylinder, before the communication with the boiler is cut off. If the stroke be six feet, and the steam shut off at three feet, the consumption of fuel will be reduced $\frac{1}{2}$ (we speak practically), if at $\frac{1}{3}$ of the stroke, it will be $\frac{2}{3}$, and so on. The reduction of the power will be in a much less ratio; and from all we have gathered from a considerable experience, the velocities of the ship will be, as the cube roots of the reduced powers. These, then, are the advantages of expansion.

In order to bring this question more fully before our readers, we have made the following calculation relative to the engines and boilers of the *Great Britain*, and which will at a glance show what will be the consumption of fuel per horse per hour—the power exerted—the cubic feet of steam per horse per minute—the cubic feet of water to be evaporated per horse per hour—and, though last the most important, what we conceive will be the velocity of the ship, with full steam pressure, and with expansion from $\frac{1}{6}$ to $\frac{2}{3}$ of the stroke, giving the results for every *six inches*—from 12 inches to 54 inches, or $\frac{2}{3}$ of the stroke.

Engines 88 inch cylinder; 6.0 stroke; 228 feet per minute: 294 horse power each.

Expansion in inches of the stroke	12	18	24	30	36	42	48	54
Horse Power with dense steam	245	220·5	196·0	171·44	147·	122·	98·0	73·5
Horse Power during expansion	44·59	61·96	79·38	91·00	101·87	117·18	107·7	101·87
Total power, whole stroke	289·59	282·46	275·38	262·44	248·87	229·68	205·7	175·37
Total power with 4 cylinders, as *Great Britain*	1158·3	1129·8	1101·5	1049·7	995·5	918·72	882·8	701·48
Contents of cylinder at this expansion	211·15	190·	167·	147·8	126·7	105·6	84·5	63·4
Cubic feet of steam $2\frac{1}{2}$ lb. above the atmosphere per horse per minute	27·6	25·5	23 5	21·5	19·5	17·5	15·8	13·7
Cubic feet of steam at the atmospheric pressure per horse per minute	32·5	30·1	27·75	25·4	23·0	20·6	18·7	16·2
Water, per horse per *hour*, to be evaporated	1 14	1·09	·98	·912	·840	·726	·66	·571
Coals per horse per hour, at 8 lb. per horse	9 0	8·51	7·74	7·12	6·55	5·87	5·15	4·5
Tons per 24 hours	111·5	103	92	80	70	58	45·5	34·
Speed of vessel with paddle wheels	13·9	13·8	13·7	13·5	13·25	12·9	12·4	11·7
Speed of vessel with screw	11·6	11·50	11·40	11·25	11·1	10·75	10·3	9·85

This table corroborates Mr. Eny's general reasoning, but we differ in detail arising from different estimations of the *full* power, and we would suggest to Mr. E., that he is obviously incorrect in assuming the "evaporation of a cubic foot of water to be equal to one-horse power," because that depends entirely on the rate of expansion used in any particular engine.

We may remark that we have constructed the foregoing table on the plan laid down by Mr Farey, the truth of which we have *practically* proved by indicator experiments—presuming that low pressure steam at $3\frac{1}{2}$ to 4 lb. is to be used, we have supposed its density in the cylinder to be about $2\frac{1}{2}$ lb. on the square inch, and have reduced this to atmospheric density for the calculations relating to the consumption of fuel.

We have been more liberal than Mr. Enys, and have allowed that *good boilers* can evaporate 8 lb. of salt water with 1 lb. of coal; that is, if they are kept in a fair state, by blowing off, or by the use of the brine-pump. This is no *supposition* on our part; it is a practical fact well known to most marine engineers.

The result given by us is also a minimum, inasmuch as we have only considered the *exact* quantities of steam required, and have not made allowance either for condensation, or for the waste at top and bottom of the cylinders, preferring that our readers should estimate this according to their own views, as far as our experience goes, we believe the allowance ought to be about $\frac{1}{20}$ of the whole quantity.

But has Mr. Enys any reason to conclude that these engines are to be worked expansively (we of course assume that he is not in any way connected with the undertaking)? We think not; and that such is not the intention of the engineers. We have noticed that she is fitted with ordinary sliding valves, arranged (with a lap of $2\frac{1}{2}$ inches, and stroke of 11 inches) to cut off the steam at $\frac{3}{8}$ of the stroke, we suspect that the separate expanding apparatus is to be used in fine weather, as in most steamers of large class; and it will be observed that Mr. R. Hill expressly states that the cranks are placed in opposite directions, and not at right angles (p. 254); and, further, the construction of the boiler is proof that the engines are occasionally intended to exert their full power, say an average pressure on the piston of 14lb. per square inch.

We are inclined to be thus particular with reference to this point, because our professional knowledge has been questioned, in having made the statement that the grate surface is "less than half the proper quantity." We are, however, hardy enough to reiterate this assertion; and further to say (if any dependence is to be placed on the drawings), that a more unscientific or badly arranged boiler could not be devised. We have made a careful analysis of its properties, and it bears out our views that it is constructed (by the amount of its absorbent surface) to supply steam for the full power of the engines, at which the consumption of coals will be fully equal to our original computation, namely, 129 tons per day. It is as follows:

Fire surface of the six boilers	= 2220	square feet.
Flue surface do.	= 11870	do.
Total surface	14,090	

If the total surface be divided by the total horse power, we shall have 14090 ÷ 1176 = 12 square feet per horse, and the grate surface 2 feet × 6 × 24, = 288, ÷ 1176 = ·245 of a square foot per horse!

We have no disposition to cavil about words, but think we may call the practice of our first engineers *proper*, but certainly not *usual*, in as much that in this very case there is an exception to the rule, and a straining after novelties at the expence of that which is useful. We here find that we have more than the *proper* quantity of absorbent surface, and less than one half the grate surface, and the result will be a very indifferent ratio of evaporation, as will be discovered when it is too late.

The size of the air-pump must of course be large enough to suit the extreme power of the cylinders, and cannot be adapted to various grades of expansion. With respect to the large condensers, theory taught us the doctrine as that propounded by Mr. Enys—the larger the better; but, from actual observations and practice, we find it is not correct, and that Mr. Watt was right in constructing his condensers of the same capacity as his air-pump. The proportion of Mr. Watt for his air-pump is about a sixth of his cylinder contents; and it is reasonable and just, the steam rushing from the cylinder, is condensed in detail, and the air-pump, at *one stroke*, clears the condenser of whatever vapour may remain. In the *Great Britain* this vapour *will accumulate* in the condenser; being between 7 and 8 times larger than the pump, which has no power to clear it; the condenser becomes hot, and no extreme quantity of injection water will keep it cool. We may or may not be correct in our view of this matter, but practice supports it, as our readers will see by reference to our last December number, page 399, vol. V., in which we have detailed the proportions used by some of our most eminent engineers.

We have little more to say regarding the probable speed of the *Great Britain*. We believe the factor 1400 to be applicable, having found it correct in very large vessels; and we see nothing in the construction of the *Great Britain* to render it inapplicable; presuming that the resistance (in all cases of similar form, as it regards the sharpness of the water lines) is very nearly as the areas of the immersed midship sections; lengthened experience and experiments with a great number of vessels have proved this. In this case our data is meagre, and we have no desire to carry the subject further, especially as it is probable that an actual trial of the *Great Britain* will soon settle all the questions in dispute.

We close with the remark, that however we dissent from the views of her engineers in matters of detail, we most sincerely hope that we may be found false prophets, and that the *Great Britain* will prove to be superior, if possible, to her sister vessel the *Great Western*, and that the proprietors will have every reason to be proud of their speculation.

THEORY OF ARTESIAN WELLS.

A French pamphlet, from which the following translation is made, has excited considerable interest in France, and is, up to this time, in constant requisition by the numerous visitors to the scene of M. Mulot's labours at Grenelle. Our readers, however, will have the goodness to observe, that although we present it to their notice, partly on account of the notoriety which the author's views have obtained in France and partly because it is important to consider ingenious arguments on both sides of a question like this, at the same time we feel bound to dissent almost entirely from the author's explanation.

If the ingenious and eloquent Parisian had been favoured by previous acquaintance with the phenomena of springs as exhibited in the extensive mining operations of this country, it is probable that his surprise would not have been so mightily excited by the Artesian fountain at Grenelle, and he might possibly have entertained a different and more generally received opinion as to its origin.

A grand Experiment; or the Well at the Abattoirs of Grenelle.

Chapter I.

Exposition of the Subject; false attempts at Explanation.

This work which has discovered to the city of Paris the source of an abundant supply of water, has been not more remarkable for the boldness of the conception which gave rise to it, than for the perseverance with which the design has been followed out. In the bosom of the capital M. Mulot has opened a sort of aqueous mine, rich and magnificent; and for this great boon the Parisians are unanimous in their expressions of admiration and gratitude. The sight of the ascending stream rushing upwards from so great a depth beneath the surface has daily attracted crowds of visitors. After the first gratification of their curiosity, the attention of this multitude is naturally directed to the cause of so extraordinary a phenomenon, and the desire for information on the subject corresponds with the admiration it excites. Each successive visitor asks himself, or inquires of those around him, whence *can* proceed so impetuous a stream? what force impels it? what immense reservoir feeds it? in what part of the earth is deposited this fruitful supply, and by what passages and communications does it find access to the extremity of the vertical tube which M. Mulot has forced into the bowels of the earth? The scientific men of the present generation have endeavoured to answer these questions. Referring to the very simple means which human ingenuity has long since employed for embellishing our gardens and public places with jets of water, they have said.—At a certain distance from Paris, and in the upper stratifications of a soil more elevated than Paris itself, there exist vast reservoirs fed by the infiltration of rain water and of melted snow. This water there sinks to great depths below the surface, and, flowing in subterranean sheets, the augur of the engineer discovers it at a spot far distant from where the earth first received it, and after he has thus succeeded in boring down to it, the liquid element naturally ascends to the surface through the vertical issue which he prepares for it. This is then a real *jet d'eau*. Nature has placed the first, that is, the descending branch; the engineer places the second, the ascending branch; the machine is perfect.

From this explanation, however, we entirely dissent, and fear not to affirm that under such circumstances water never could rise on the principle of a syphon. In order that a jet of water, whatever may be its dimensions, shall work with certainty, one condition is indispensably necessary, viz., the uninterrupted continuity of the curved tube charged with conducting it from the reservoir above to the less elevated region where the jet is required to play. All the force of ascension in the second branch of this tube ought to be derived from the accelerated velocity of the water in the first branch, and this acceleration would be as inevitably broken and annihilated by any obstacle, as by the entire destruction of the continuity. Now, in the interior of the earth, to whatever depth we may penetrate, we can find nothing resembling continuous tubes; everything there is more or less friable, casual, and irregular. Thus, whatever pains the engineer may take in order to reach by the smaller end of his vertical tube the surface of a subterranean sheet of water, it will all be useless unless by a very astonishing fortuitous accident, he should meet with another tube of the same calibre, ascending without rupture to the upper reservoir. If, as some believe, it be in the mountains of Burgundy that this reservoir is placed, is it possible to conceive the existence of a continued oblique tube ascending from beneath Paris to the neighbourhood of these mountains? Besides, no one appears to doubt that M. Mulot's choice of a situation for his well was perfectly arbitrary, and therefore if he had attempted to construct one upon the Place des Invalides or in any other part of the capital, he would have equally succeeded. Hence, then, it will be granted that in and around Paris it would be possible to dig an indefinite number of Artesian wells, all which would be fed by the mountains of Burgundy; and in order to explain this, we must picture to ourselves the uppermost beds or strata of earth under Paris and the surrounding country within a circle of two hundred leagues diameter, invariably woven into an inextricable net-work of which each filament is an unbroken tube. Assuredly nothing like this exists.

There are others who have sought to explain the rise of water by conceiving two concave vases, or two immense cisterns of unequal diameter, placed one within the other, the basin of Paris occupying the centre. They imagine that the margins of these vases extend from the mountains of the Vosges on the east, to Havre on the west; and from the plains of Flanders on the north, to the mountains of Burgundy on the south. They suppose that between these two vases there is a space filled with sand. The rain water which penetrates into the pores and cavities of the sandy district is retained there by the dense matter of the two vases. The water maintains the same level through the whole of the sandy space, but it does not penetrate into the basin of the higher or smaller vase. Hence it follows, that by boring vertically through the basin, the water confined in the sand will instantly rise to the height of that which exists in the circular reservoir all round it. This is certainly a very amusing geological disposition of things, but unfortunately it is supported neither by facts nor reason. A continued vase with a double bottom, more than a hundred leagues in diameter, fixed in the bosom of the earth! A vase whose inferior limits, as shown at this day by the well of Grenelle, are no less than 1690 feet deep, and into which flow all the subterranean waters from all the surrounding shores! What a gigantic disposition of things, and no less gigantic than admirable! A god must he have been who founded Paris, and cradled the capital of the world in the centre of this marvellous vase! Ridiculous idea to imagine, even if this vase exist, that it should be unbroken throughout so vast an extent. Do we not know on the contrary that the vase is cut up and divided into many irregular compartments? Throughout the prodigious extent of space which is claimed for the field of this theory, as at Tours, at Elbœuf, at St. Denis, and St. Ouen, numerous Artesian wells have already been constructed, and all these wells of many various depths are much shallower than that of Grenelle. Has each well, then, its respective vase encased in the general vase, and resting upon its own particular bed of sand? If such be the fact, we must suppose that a great number of Artesian stages exist in the general vase. But in this case, why did not the water rise at Grenelle when the augur had reached one of these elevated stages, that of the St. Ouen for example, so near to Grenelle? Does not the Artesian vase of St. Ouen extend to the abattoirs of Grenelle? If not it must be singularly circumscribed. It has nevertheless supplied for fifteen years two constant fountains, and the Artesian wells of Tours, Elbœuf, and St. Denis are equally inexhaustible. Doubtless we may construct an indefinite number of Artesian wells upon the surface of the country which surrounds Paris; indeed this experiment has been made in various places, and according to a report addressed to the Academy of Sciences, dated 15th March, 1841, we find that "many of these wells bored at the bottom of a valley, yield no water, whilst others fixed upon the side of a hill, furnish an abundant flow." What inexplicable mystery in the hypothesis of a sheet of subterranean water fed by rain, and springing up only from inferior cavities to establish a horizontal equilibrium. Again, if it be said, that the general vase, the centre of which is placed beneath Paris, receives throughout the whole circle of its sandy borders the rain water from the Vosges, from Burgundy, from Bretagne, and from La Vendée, we ask how it is that all these waters, flowing over slopes of many different inclinations, but all of them more or less steep, and always repairing to the same cavities, has not long since choked up its own passage by the sands which it must have carried along with it. The great sands in the Delta of the Nile, in the Gulf of Gascony, and in the Aigues Mortes, all teach us the inevitable results of continual deposits. And if we suppose that the two cisterns here spoken of, are formed of a substance impermeable to water, such as glass, or porcelain, or baked earth, how has it happened, that buried in the earth during many ages, they have never experienced any shock or accident which would have broken them to pieces? It is evident if any thing of this latter kind had ever occurred, that the water which had lodged in the interval between the two vases, would naturally pass through the fissures and ruptures into the cavity of the upper vase, thus destroying the internal arrangement of the hydrostatic machine, whose existence has been so gratuitously assumed. Besides, if this machine really exists under the basin of which Paris occupies the centre, if it has its circumference at Havre, at La Fleche, in Burgundy, and at the foot of the Vosges Mountains, we could not construct Artesian wells at any of these points, for throughout the whole of this circumference, the aqueous reservoir would be only at its origin and would have no vase to rise into. And yet, nobody doubts that in the neighbourhood of all these boundary districts, the Artesian well has as much chance of success as at Paris, St. Denis or Elbœuf. It is also known that the Artesian wells of Tours have succeeded, although on the south side of the basin of Paris.

By the simplest laws of physics, we shall now show how imaginary is this Artesian source of water. We are told that through immense beds of sand the water sinks from the surface of the soil into the grand subterranean cavity. But who does not know that, when obliged to sift itself through a bed of sand, however loosely disposed, water loses all motion, except a kind of slow and difficult leakage. Towards the base of our artificial sandy fountains it comes only drop by drop, and it loses in its course all the velocity due to the space it has passed through, and all the pressure due to its weight. If the spout which discharges the water should open upon a bent tube with an ascending branch, the water would not rise above the level of the space which it already occupied in the base of the fountain. This would be its whole hydrostatic power; and if the ascending tube were full of sand, it would rise something above this same level: but, in that case, the effect would be due entirely to capillary action. The most striking objection, however, still remains. During the summer, what becomes of the rain water immediately after falling. The greater part, instead of sinking into these profound depths, is evaporated and carried off through the atmosphere, and it is very seldom that either our fields or gardens, the morning succeeding a storm, show any traces of moisture more than a foot in depth. Would not the alternation of wet and dry weather cause an incessant variation in the flow of an Artesian well, seeing that this incessantly varies the supplies of our fountains and the height of our rivers? Oh, no! in spite of all this, the Artesian wells have always the same volume, and in truth, acknowledge neither summer nor winter. We shall, hereafter, explain the constancy of Artesian wells. But, in the first place, we must consider another gratuitous supposition. Let us first explode all error, we shall then more easily arrive at the truth. It is said, by some, that the rain water and that which proceeds from the melting of snow, sink into a subterranean horizontal region void of solid matter, but hemmed in above and below by two beds of impermeable clay. Upon the upper one reposes an enormous mass of chalk and other calcareous stone, which bears with all its weight upon the volume of water underneath, and this weight forces the water to rise vertically at every place where an opening is made down to it from the surface. In this hypothesis all the mechanism of ascension derives its impetus from this force of pressure. The origin of the water is a matter of indifference, it may have come from Langres, from the Vosges, or from the Jura mountains; its complete inertia is the same when it has arrived in the centre of the basin, beneath the abattoirs of Grenelle. The process of filtration, which has brought it to this place, gives it at least no inclination to ascend; it has, therefore, waited patiently to be impressed by superior masses, in the same way as the fluid, which is motionless in the body of a pump, waits only the action of the piston to force it upwards. But to produce this discharge, the piston must move—it must, in reality, press upon the water which it brings or sends up—in fact, it must work up and down in the barrel of the pump, filling at each successive point of its motion the whole area of the barrel. If we suppose that the subterranean sheets of water rise only because they are pressed by the solid masses above them, we must also suppose that these masses really *act*, as no ascension can be obtained except on this condition; that they actually *fall*, so that, in digging the well of Grenelle, there finding water 1600 feet below the surface and causing it to flow impetuously more than 80 feet above the surface, M. Mulot would have expended so much art and courage only to provoke a disastrous crash in the strata beneath Paris. Evidently, however, and very happily, we may add, this has not been the result. The laws of gravity are universally the same. Place on the surface of the earth a sheet of water of any extent; fill, for example, the basin of the Champ de Mars with a body of water which shall remain there; endeavour then to gain dominion over this sheet of tranquil water through solid masses of chalk or clay. In order that these masses shall remain in position superimposed on the stagnant water, they must be fashioned into vaults and arches, and there they will be supported without pressing upon the water of the basin. If, for a single instant, they should rest upon this water, they would inevitably sink and be submerged in it, and the result would be a chaos of *debris* saturated with water. But in the bosom of the earth no solid masses are found in the shape of vaults, neither are there any sheets of water, either confined or at liberty. It is true there are here and there, in the cavities of rocks, in subterraneous grottos, and at the foot of all great mountains, a few pools of water, or more often there are rivulets fed by the infiltration of rain water, and serving to supply fountains which rise at a short distance, and which generally contribute to the formation of streams and rivers. But nearly all these are found on the surface, none of them can occupy a space of any extent in the lower beds of the earth, because they would soon fill up such spaces, by depositing the sand which they bring with them. Besides, in any case the subterranean waters impelled only by a broken, unequal, irregular movement, would have no disposition like those of a *jet d'eau* to rise above the inclined bed over which they had flowed. A *jet d'eau* in exercise is in fact a pendulum, it is free and regular in its movements, its mechanism is the same, and the same cause produces it.

Now if a pendulum, starting from any altitude whatever, should meet in the course of its descent towards the vertical line, any obstacles which retard it, the motion will either stop at this vertical line, or at least the oscillation will be very feeble, since it will correspond to that feeble force of acceleration which the obstacle may not have entirely destroyed. In the same manner, the liquid pendulum, that is, the column of water, throughout its descent to a horizontal situation, rigorously requires, in order to an equal rise in the ascending branch, that all its motion and all its acceleration should be truly effected in a continuous canal, entirely filled by the water itself, by the water alone, and that so perfectly as to be inaccessible even to atmospheric air.

We shall now describe a simple and conclusive experiment. Upon the bottom of a basin, place an upright tube with an opening entirely through it; and on some stormy day fix the basin beneath the water pipe of a house. The tube will be found to contain some water at its lower end, but only to the height of that which is also found in the basin around it. Not a single drop will rise above this level because all the force of its fall is expended on the basin itself. But let us now replace the straight tube by one which is curved upwards from its lower extremity, and we shall find that the force of the fall, being confined to the continued column of water which must entirely fill the tube, will cause the water to rise in the ascending branch to the same height as the top of the descending branch. We have now then constructed a real *jet d'eau*, because we have made use of the only apparatus which can produce one.

It is quite certain that the crust of this earth no where contains an apparatus of this kind; the flowing of an Artesian well cannot therefore be assimilated to a *jet d'eau*. Some other explanation then must be sought, and in order to be satisfactory, it must be one which answers all the conditions of the phenomena.

The explanation we are about to give is necessarily of this kind, since it is derived from an universal principle of nature.

Chapter II.

The true explanation.

The globe which we inhabit is manifestly a focus of action and heat, which has its greatest energy at the centre of the mass, and which, from this central point, works incessantly to carry matter from the interior to every point of the surface, and which, in this constant effort, meets with a gradually increasing resistance from the successive strata composing the crust of the earth.

This exterior resistance constrains the central fire to divide and attenuate the matter of the interior, and to sift it, as it were, in minute particles through the pores of the general envelope.

From this internal elaboration, and this subtile oozing out, arises the continual emission of interior caloric, an emission which necessarily takes place in a radiating form; that is to say, each jet or steam of caloric escapes and flies off in a direction perpendicular to the surface. Here then is the first analogy with the vertical stream of water which issues from an Artesian well. Each pore in the terrestial covering is an Artesian well of caloric: and so again is each pore in the surface of every star in heaven an Artesian well of light. These Artesian pores in the crust of the earth being infinitely numerous, it is through these that the central fire impels, in a state of the most minute subdivision, a great part of its interior contents.

This way of escape, however, is not every where sufficient; the central action does not appear to succeed in attenuating every substance to such a degree as to effect its expulsion through such exquisitely minute apertures. At many places under the terrestial covering, opposing masses are crowded together, some in a state of gas, others in a vapoury state, others again in a liquid form, and others possessing the consistency of solids, but at the same time broken and confusedly mixed together; and all these substances, whether gases, vapours, liquids or solids, are agitated by a movement whose impetuosity equals its disorder.

The time is now come when the exterior resistance is suddenly conquered; the crust cracks—a *volcano* is open, and its centre shoots forth immense jets, at first of gas and vapour, then of liquid water, then of burning lava. It is a frightful pit, suddenly thrown out by the irritation of the central fire.

We know that the volcanoes of Iceland frequently vomit forth torrents of gas, vapour, and liquid water, which cannot have come from the sea, as its composition is different from that of sea water.

Let us imagine, for a moment, what would happen if at the instant when a volcano was about to burst forth, its crater could be contracted into a straight tube like that of Grenelle! What a magnificent Artesian well would then be displayed! What force and height would there be in the jet sent forth!

But let us not forget that every volcano is a kind of relief and vent for the interior tumult of the earth. It resembles the pimples and boils on the skins of men and animals. In the normal or regular state, the volcano is silent, and so in a state of health is our skin smooth and sound.

Thus, at the present time, when no terrestrial volcano is in a state of formidable eruption, the globe, like a sound and healthy man, quietly and uniformly transpires through every microscopic opening in its surface, the superabundance of its interior productions; and under their general covering these productions are chemically elaborated, so that each may occupy its proper region. The water in a state of vapour, which is directly formed in the bowels of the earth, even finds a passage through strata of the denser character. If near the surface it meets with argillaceous masses, it requires an increase of effort to traverse them. Below these the vapour thickens, condenses, and takes at length the liquid form: and then, far from being oppressed by the contact and weight of the solid masses which cover it, the water is constantly, if we may use the expression, in a state of insurrection against them, and continually seeking to rush up through them, or throw them off.

Hence it is that if human industry, exerting itself at the surface of the earth, shall pierce this surface and force down a vertical pipe into the aqueous region, the impatient water seizes upon the means of escape, and fully liquified by its very first movement in a passage so contracted, runs impetuously through its whole length. Arrived at the orifice, it flows over, and even mounts above it. The vertical jet has a force proportionate to the depth of the excavation which was necessary to arrive at the water.

This circumstance is remarkable, for the contrary would be the case if the Artesian fountain were produced like an ordinary jet d'eau, by the simple weight of a liquid column falling from an elevated reservoir, and working to regain its level. We know that in every hydraulic apparatus, the effective action is weakened in proportion to the extent of surface which the liquid has to pass over, and to the friction it has to overcome.

But not only is the force of the Artesian jet much greater in proportion to the depth of the excavation—the heat of the liquid itself shows clearly that the augur of the well sinker has more closely approached the producing and expelling fire which exists in the centre of the globe.

The source then of Artesian eruptions, is the same as that of volcanic eruptions; it is the central action of this terrestial globe; it is the formidable Power, which, during the infancy of the world, launched out upon its primitive surface alike the isolated cones and long unbroken chains of lofty mountains, and which from time to time is exerting efforts to raise new mountains. This marvellous Power is that sole and universal Force, that Expansion which is constantly in exercise throughout all material being; it is none other than the grand Principle, the Soul of nature, the producer of *life*, which under the eyes of all men, spreads and developes itself throughout the substance of every organized being, and whose expression and sentiment each one of us exhibits in his own person.

REVIEWS.

Walks through the Studij of the Sculptors at Rome, with a brief historical and critical sketch of Sculpture from the earliest times to the present day. By Count Hawks Le Grice, K.S.G., Chamberlain of Honour to his Holiness the Pope, &c.

"It is with great pleasure," says the *Diario di Roma*, "that we announce this new work, by a learned Englishman; it contains descriptions of works in sculpture, executed by the most renowned living artists. And we may now congratulate ourselves in having, in this work, found a person in every respect qualified to do justice to living merit, and at the same time give a sure and instructive guide to direct attention to the modern productions of the chisel. Throughout the work, the Count displays profound erudition, and extensive knowledge of the arts, and much beauty of classical and poetic illustration. Hitherto, there existed no book to guide the inquiring traveller through these repositories of modern genius and taste; and hence numbers visited Rome, without deriving pleasure or profit from their inspection." In consequence of these remarks we were led to a perusal of the Count's work, from which it would appear that sculpture has attained, at Rome, a remarkable degree of perfection; and that many of the works of the nineteenth century are equal to those executed in the Augustan age.

The degradation of taste in the arts has ever been a mark and consequence of the degradation of taste in literature; and we shall find during the four great ages of the fine arts, that literature flourished. The first and most brilliant age was that of Phillip and Alexander the Great, or that of a Pericles, a Demosthenes, an Aristotle, a Plato, an Apelles, a Phidias, and a Praxiteles. The second age is that of Cæsar and Augustus, distinguished likewise by the names of Lucretius, Cicero, Titus Livius, Virgil, Horace, Ovid, Varro, and Vitruvius. The third age was in the time of Medicis; the most glorious age of Italy, when learning was restored under the Popes Julius II and Leo X, and when flourished a Michael Angelo, a Raphael, a Titian, a Tasso, and an Ariosto.

But it is time that the Count should speak for himself. In describing an allegorical bas-relief, the author says—

"This allegory is intended to show the difficulties which the arts have to contend with, from the ignorance or malevolence of those who can neither understand their value nor feel their influence, and whose souls are so materialised, if we may be allowed to use the expression, philologically not metaphysically, as to appreciate nothing which is not gross. For such souls, the noblest productions of the chisel and the pencil possess no attractions; the works of genius and of taste are to them as so much waste marble and canvass; and there are not wanting some, who would gladly wage a war of extermination against the productions of the chisel and the pencil. Even in Old England, my own, my native land, the land of commerce, wealth, power, freedom and science, how comparatively parsimonious is the encouragement of the fine arts, and how comparatively unknown are sound artistic principles! Far from us the ignominy of disparaging our adored country, which absence has served only to endear to us still more: but it is time that England should take her stand among the nations of civilized Europe in relation to the fine, as she does with regard to the useful, arts. It is time that a fair portion of that wealth, which is so often profusely expended on less refined enjoyments, should be appropriated to the encouragement of the liberal arts, particularly of sculpture and painting; and we should no longer bear the reproach of employing foreign artists, whilst we neglect to promote the cultivation of national artistic taste and talent."

The Count again observes—"The foreigner finds no obstruction in Rome to his progress in the fine arts; but, on the contrary, enjoys indiscriminately with the Roman, all the facilities that Rome commands. Hence, we find that Thorwaldsen and Fogelberg have abandoned the frozen regions of the north to bask in the sunshine of their fame in the more genial clime of the south. These eminent sculptors have both won laurels for their country. France, too, is not backward in the race of glory; and her splendid academy in Rome will perpetuate her series of distinguished artists. Russia, too, extends efficient patronage to her native artists; and at this moment she maintains in Rome 30 pensioned students. Naples, also, has a Royal Academy here, under the direction of Baron Camuccini, the first of living painters; and Berlin, Spain and Portugal, have also their respective academies in Rome, as have several other nations, too numerous to be mentioned. Thus does Europe testify, that Rome is in truth the only school for the fine arts. And must we make one painful exception, and that exception our own, our native land? Yes, it is our painful duty to state, and we do so, in the humble hope of drawing attention to the fact, and remedying the evil, that England, with all her wealth, sends but one solitary artist to Rome from the Royal Academy, and that once only every three years! How, then, can she compete with other countries in the true classic style of art."

In speaking of the extraordinary progress of sculpture, our author observes—"The group of Nestor and Antilochus by Alvarez, executed during Canova's life time, the Discobulos of the late Kessels, the Achilles of Albasini, and the Mercury of Thorwaldsen, astonished the whole artistic world; and yet they essentially differ in style and character from the works of the immortal Canova. These productions have aided in producing a revolution in style, which is likely to be permanent; and all with one accord now agree to follow the pure style of Grecian sculpture. Denmark has now to boast a Thorwaldsen; Sweden a Fogelberg; England a Gibson and a Hyatt; Ireland a Hogan; Scotland a Macdonald; Italy a Tenerani and a Finelli; Spain an Alvarez; and Holland a Kessals, all educated in Rome, and essentially Roman sculptors of the revised school of Grecian art."

It does appear that nation after nation and century after century have been able to do little more than copy the Grecian masters. We know the use Virgil made of Homer in his Æneid, and of Theocritus in his pastorals; and we find that Horace applied several places, out of Anacreon and other lyrics, to his own purpose: therefore, why should we preclude the modern sculptor from copying from Grecian art? "There is," says the Count, "but one school of art that can lead to perfect design and execution, and that is the school of Grecian art. Any deviation from the Grecian type must necessarily be a departure from the only true standard. The choice of a subject, the attitude, and in some instances, the drapery, are all of comparatively minor importance, provided the artist has made the severe, classic style of Grecian art his canon. The works of the greatest modern artists should not be taken as models; to copy their style would be to give a translation from that which has been already translated; and he who suffers himself to be carried away by his admiration of modern productions, should bear in mind that their authors drew their excellence from no living artist, but from the great masters of ancient Greece, whose productions they have profoundly studied. When the great Canova blazed in the zenith of his fame, many artists became imitators of his style, and their copies were mere shadows of the great original; they wanted the soul that animated his statues: and the exquisite essences, which Canova extracted from Grecian art, had evaporated in the attempt to transfer them. That the works of any eminent modern artist may be consulted with advantage we freely admit: they serve as a guide to the ascent of an eminence difficult of access; they inspire the artist with ardour; and encourage, while they urge him onward by their counsel and example. They are so many auxiliaries to the other powerful excitements to glory; and their combined influence has fired the breast of our talented countryman, and raised him to the proud eminence from which his genius (Gibson) sheds such lustre on his name and on his country."

Our author seems to have forgotten our distinguished countryman, Mr. Baily, who, says a recent writer, "is one of those instances, too frequent in the history of art, in which the rewards of genius of the highest order have been too long deferred, and too sparingly bestowed. Gifted with a sense of beauty, akin to the spirit of his great countryman Flaxman, and a boldness of conception not unworthy in some of its exhibitions, of the greatest of sculptors, Michael Angelo, he has yet been destined to see men, less highly endowed, step before him into the light of patronage, and commissions pass by his neglected studio, on their way to foreign lands." "It is not to be doubted," continues the writer, "that had Baily been found by his countrymen in the metropolis of his arts, his genius must, amid the strong lights of the everlasting city, have long ago secured for him, in spite of his English name, those triumphs which it is as little to be doubted yet await him." It appears to us that the removal of our Baily from the eternal city, is something like transplanting a rare exotic out of a warm and genial clime, to a cold and sunless country, where if it but chance to put forth its buds, a hard and a killing frost nips them ere they blossom and bear its precious fruit. Abbé du Bas, in his reflections on poetry and painting, has collected a great many observations on the influence which the air, the climate, and other such natural causes, may be supposed to have upon genius.

Before we close this interesting book, we are tempted to make one or two more extracts, which will fully prove the Count's abilities for the task he has undertaken. In describing the *Triumph of Apollo*, a bas-relief by the celebrated sculptor Thorwaldsen, the Count observes:

"This bas-relief represents Apollo attended by the Graces and by Cupids, as he conducts the Muses, eminent poets, and promoters of the fine arts to Mount Parnassus. The first figure is Hyperion, the father of Aurora; he is on the wing, bearing a torch, and is conducting the winged Pegasus. Apollo appears seated in his chariot, drawn by the horse of Helicon; his brow is wreathed with a laurel crown, and in his hands are his harp and plectrum. With impassioned air he sweeps the silver strings, which fill heaven with melody, and render the very stones harmonious. Next follow the Graces, entwined with festoons of flowers, and conducted by an infant Love, while the god of the Cyprian bowers is on the wing, and scatters roses on their decoy path. The fair daughters of Jupiter and Euphrosyne appear in unveiled loveliness, and glide along with the lightness of summer zephyrs. The first among the Muses is Calliope; presiding, as she does, over eloquence, she holds in her hand a scroll, such as Demosthenes might have thundered from as he paced with earnest step the solitary beach of his native Attica. Euterpe, as she plays her favourite lute, joins Terpsichore in the merry dance. Thalia and Melpomene follow, with the characteristic symbols of comedy and tragedy, the pedo or pastoral staff, the mushe and club. Erato, the muse of love, is crowned with roses, and attended by a winged genius with a harp, the golden strings of which he touches lightly with his dimpled fingers, and the air resounds with the soft sighs of the votaries of Erato. Polyhymnia is known by her meditative air, and presiding, as she does, over song and rhetoric, she holds in her hand a scroll. Urania is at once recognized by the globe as the Muse of Astronomy; and Clio, the Muse of history, follows, and is inscribing with a pencil of light, on the annals of Fame, the names of those whose exploits have entitled them to immortality. Mnemosyne, the mother of the Muses, follows near to Clio; she is closely draped, and moves with slow and maternal air. At a short distance from her is Homer, the father of heroic song, who is preceded by a winged genius bearing a palm branch and a wreath of flowers, emblems of his pre-eminence and renown. The venerable bard lifts his sightless eye-balls towards heaven, the source of his inspiration; and, whilst his fingers sweep the strings, his lips give utterance to those epic strains which enrapture gods and men. "Homer," says a modern writer, "transports us to a new and ever fresh creation, in which, though much is calculated to astonish, all appears real, substantial and imperishable. Olympus, with its deities on their golden seats, lies open to our view, in form as palpable as the glorious towers of Troy, the sacred Scamander, and Ida with its hundred springs. Prodigies become familiar to us.'"

Such is a brief outline of the bas-relief before us, which combines so many classic beauties of such various characters, that even the *disjecta membra* delight us; but, to catch the spirit of this sublime creation, let us but cast an eye over it for a moment as a whole, and we shall thus learn to appreciate its surpassing excellence, and to estimate, as we ought, the genius of the man whose creative power invented, and whose artistic skill executed, "The Triumph of Apollo."

We will conclude our extracts with a description of the "Terrestrial and Celestial Love," a bas-relief by Gibson, R. A. "This relief is composed of two figures, one representing Terrestrial the other Celestial Love, under the forms of two winged Cupids. They are both contending for the soul, under the form of a butterfly, the emblem of the fair Pryene, who was about to be immolated on the altar of Venus. Celestial love appears in the act of descending from above; he has rescued the soul from Terrestrial Love, and is staying his hand to prevent its pollution at so foul a shrine. In the struggle, Heavenly Love has triumphed over earthly desire; and holding aloft the divine Psyche, he plumes his ethereal wings to bear her aloft to purer and brighter realms. Terrestrial Love holds the torch of Hymen, which he has lighted from the flame burning on the impure altar of Venus; and at the foot of the altar are the fatal instruments of his power, the bow and arrow, and also a pine-apple, the symbol of love.

"This bas-relief is an illustration of one of the tenets of the Platonic philosophy. Plato compared the soul to a small republic, of which the reasoning powers were placed in the head as in a citadel, guarded by the senses, and the tumultuary portion he placed in the inferior parts of the body. He was the first heathen philosopher who maintained the immortality of the soul upon solid arguments, deduced from truth and experience; and he held that the soul, being an emanation from the Divinity, can never remain satisfied with objects or pursuits unworthy of their divine original. According to Plato, supreme happiness is attainable by removing from the material and approaching nearer to the intellectual world, or, in other words, by governing the passions according to the principle of the moral law; and thus, by the practice of virtue, exalting ourselves to an imitation of the Divinity, from whom the soul has proceeded, and to whom, when its affections are thus purified, it is finally to be united in supreme felicity. The beautiful moral thus conveyed by this exquisite composition is too obvious to be dwelt upon. Who has not experienced the struggles of the sensual with the spiritual man? and who has not felt, within his breast, those lofty aspirations which lift the soul above the debasing influence of unholy desire, and fix its affections on another and better world? Nor is the idea of two Cupids struggling for the soul recommended by the simple beauty of its moral alone, but also by its classic taste, for the ancients recognised a celestial as well as a terrestial Venus. "I will not assert," said Socrates, "that there are two Venuses; but as I see that there are temples consecrated to the celestial as well as to the terrestial Venus, and that they sacrificed in the former with ceremonies more sacred and with victims more pure, I presume that two goddesses of that name do exist. The vulgar Venus inflames the passions, and the heavenly Venus invites to virtuous actions.[1]

"It were superfluous to dwell on the artistic merit of this relief; it evinces a mind cast in a classic mould, and possessing a deep and refined sense of the beautiful in conception as well as in form; nor can the harmonious lines of the composition be too much admired or too highly praised."

From our extracts we are sure our readers will agree with us, that the sculptors of Rome have good reason to congratulate themselves on having found in Count Hawks le Grice one who has not only brought their productions favourably before the public, but is very likely to perpetuate their memory. We are indebted to Pliny and Pausanias for a knowledge of some of the noblest pieces of ancient sculpture, many of which have perished; and whatever may be the fate of the works which the Count describes, he is very likely to transmit to posterity their merits, and the honoured names of their authors. We understand that the author has received numerous literary distinctions from various learned bodies; and we have no hesitation in saying, that his "Walks through the study" more than justifies the opinion held of his merits. The style is characterised by an elegant simplicity and classic purity, and the work is enriched throughout with such felicity of illustration and fecundity of invention, as shed a golden glow over its pages and the productions which they describe.

Railways, their Uses and Management.—London, Pelham Richardson, 1842.

This is a very interesting epitome of all the railways that have been executed and in progress in this country, and is very ably written, affording a brief insight into their cost, working, and management. The following extract, relative to some of our principal engineers, will be read with some interest.

"Most happy should we be if the undertaking had to depend for its success in Parliament upon its own value without the intervention of counsel, as not only would time and money be thus saved, but the real merits of the proposed work would be brought forward more honestly, or if it had not these pretensions and that recommendation, it would lose a false bolster and fall. It is well known that the skill and science of the different Engineers is frequently useless to them, with all their assured knowledge, by their failure as witnesses. Thus George Stephenson is never put into a witness-box, if his friends can keep him out, he has not the temper for cross-examination by persons he considers ignorant of the subject, and with his opinion of himself, it would be impossible to find any person he would submit to. No man however deserves more credit than George Stephenson, for the manner he has advanced himself in the world, which is in itself no greater proof of his natural abilities, than his acknowledgment of it, is of his real unaffected excellence of heart—he is however a theorist of the wildest kind, and until he became a coal owner, felt that the first things in the world were railways and the first person George Stephenson. He has, notwithstanding his energy and knowledge of coals, failed to introduce them into public use at a reduction in their price, as he promised he would, and no inland coal will do so, however much its introduction into the metropolis may interfere with the sea-born supply. His railways are not always the best or most profitable, and we think he has made a mistake also in becoming chairman of any railway company. Robert Stephenson, with a higher education is more calm and self-possessed and makes a better witness. Walker, sharp, quick and clever, may always be relied upon for all he undertakes. Sir John Rennie, however, possessed of all the knowledge on the subject, cannot stand the badgering of counsel and forgets his professional service in his gentlemanly feelings. George Rennie is too retired and modest to make known his extensive information and much mechanical knowledge under the ordinary examination of counsel—he must be drawn out, and thus makes an honest, conscientious, and intelligent witness. Young Brunel is clever and self-possessed, and would not be easily put down. Locke's testimony would look hard, matter-of-fact, and solid—economical in all its parts. Giles is hasty, anxious, but determined not to be put down; Cubitt, quiet, calm, and firm. Vignolles, energetic and fiery, looking the very personification of some new and wild theory, to be put into immediate practice by his instrumentality, would rather astonish his audience by his bold expostulations and warm support of them, than convince by his arguments and facts, except in matters of detailed and minute expense in practical experience—his evidence has, however, been largely counted on by his employers. Braithwaite is a clever machinist, with an inquiring mind; and, in our opinion, has been spoilt by being made a railway engineer; in this latter position his only experience is the Eastern Counties line, and his declaration of the correctness of his original estimates for the whole line to Yarmouth, made at a public meeting a year and a half after obtaining the act, will hardly add to the confidence of the public in his future undertakings; his self-opinion and readiness will always support him, whether as a witness or advocate. Bidder is, perhaps, the most perfect witness; for though Rastrick has the hardest mouth of any, and the most imperturable determination not to be beaten—yet Bidder, with all the same pertinacity has, in addition, an effrontery of manner (however unintentional) which defies the most resolute opposition; Gibbs is honest and straightforward, and having bought his experience on estimates somewhat dearly on the Croydon, would never again deceive himself, or others."

Year Book of Facts. London: Tilt and Bogue. 1843.

This very useful annual abounds with a store of information extracted from numerous scientific periodicals and daily papersof the past year, and which exhibits the progress of science during that period.

A Hand Book for Plain and Ornamental Mapping and Engineering Drawing. By BENJAMIN P. WILME, C.E. Part IV.

This part, like the previous numbers, contains some useful examples for reference; among others are sections of stratified rocks, titles for maps and designs, Gothic letters, &c.

NOTES ON STEAM NAVIGATION.

Slide Valves.—As the formulæ we gave on a former occasion in reference to the effect of any particular quantity of lap on slide valves, have not, we understand, been thoroughly uaderstood by the less scientific portion of our readers, it may be useful to reduce them to the form of common arithmetical rules.

To find at what part of the stroke the steam is cut off.

RULE.—Divide the cover on the steam side by half the stroke of the valve. Find by a table of *natural* sines the arc whose sine is equal to the quotient. Take the double of the arc thus found and subtract it from 90°. Find (in the same table) the sine of the remainder; add 1 to the sine thus found, and multiply the sum by half the stroke of the piston. The product will be the space travelled over by the piston before the steam is cut off.

To find at what part of the stroke the exhaustion passage is closed.

RULE.—Add the cover on the steam side to the cover on the exhausting side, and divide the sum by the length of the valve stroke. Find the arc whose sine is equal to the quotient. Take the double of this arc and subtract it from 90°. Find the sine of the remainder, add one to it, and multiply the sum by half the stroke of the piston. The product is the space passed over by the piston before the exhausting passage is closed.

To find at what part of the stroke the exhaustion passage is opened.

RULE.—Subtract the cover on the exhausting side from the cover on the steam side. Divide the remainder by half the length of the valve stroke. Find the arc whose sine is equal to the quotient. Subtract this arc from 90°, and find the sine of the remainder. Add 1 to it, and multiply by half the stroke of the piston. The product is the space passed over by the piston before the exhaustion passage opens at the opposite end of the cylinder.

All dimensions must of course be taken in the same measure, whether feet or inches. If the eccentric be so placed as to make the steam port be considerably opened at the commencement of the stroke, or so as to give a considerable lead as it is termed, the amount of the lead must be added to the cover on the steam side.

Covering boilers with bricks.—The iron platform above the boiler on which the coal generally rests, becomes quickly worn away by oxidation, and the boiler beneath it is generally much injured from the same cause, the whole top of the boiler being necessarily inaccesible, thereby imposing an insuperable obstacle to painting and even to inspection. To obviate these evils, as well as to prevent the escape of the heat, a covering of bricks set in Roman cement was some years ago applied to the boilers of the steam vessel Tagus, and has been found to accomplish its purpose effectually. Upon this covering of bricks the coals repose—the expence of an iron platform, and what is more important, the expence and inconvenience consequent upon its constant repair have thus been avoided, the shell of the boiler is preserved from corrosion, the intolerable heat of the coal boxes is obviated, and fuel saved by the conservation of the heat. The expepedient is an exceedingly economical one, and we look upon it as effectual and judicious in every respect.

We have received another letter from Greenock, signed J. G. Lawrie, respecting the formula we gave in our *Notes on Steam Navigation*, respecting the heat contained in surcharged steam, and in which our correspondent says, "I again assert, in the face of the denial in your last number, that the formula is misapplied." The best mode, perhaps, to refute the alleged misapplication, is to investigate the question by an independent method, in order to see whether the same results are obtained; and should our readers afterwards conclude that the "total misapplication" applies rather to our correspondent's correction than to our original statement, we are at least not responsible for the discourteous manner in which the intimation is conveyed.

(1) When air is heated, it expands, and the increments of volume are proportional to the increments of temperature. Every increment of 1° in temperature produces an increase in volume $\frac{1}{480}$ part of the bulk of the air at 32°. This rule has been found to apply to steam out of contact with water.—(Thomson on Heat.)

(2) The specific heat of steam out of contact with water is inversely as its specific gravity, and at 212 and saturated is ·847. From these data, the amount of advantage derivable from the use of surcharged steam may be computed.

Let t' = temperature to which the steam is raised out of contact with water.

s = mean specific heat of the steam between the temperatures 212° and t'.

v = the volume of steam at the temperature t'—the volume at 212° being 100.

x = the volume of the same weight of steam at 32°, supposing that it could be cooled to 32° without condensing.

h = heat reqnired to raise 100 volumes of steam from 212° to t'

b = weight of water in 100 volumes af steam at 212°.

c = heat required to raise the temperatnre of a quantity of water $= b$ 1°.

h' = heat required to generate from water at 60° a quantity of steam equal in volume to $v - 100$.

From (1) we have $x + x \times \frac{1}{480}(212 - 32) = 100$ or (since $\frac{1}{480} =$ ·002083) $x + x \times ·002083 \times 180 = 100$: · $x\,(1 + ·37494) = 100$

or $x = \dfrac{100}{1·37494}$

From (1) also we get $v = 100 + x \times ·002083\,(t' - 212)$ which by substituting the value of x previously found becomes $v = 100 + \dfrac{·2083\,(t' - 212)}{1·37494}$

From (2) we find $100 : v : : ·847$: specific heat at the temperature t' which is therefore $\dfrac{·8470}{100}$ hence

$$s = \tfrac{1}{2}\left(\frac{·8470}{100} + ·847\right)\text{ or by substituting the value of } v.$$

$$s = \tfrac{1}{2}\,(·847 + \frac{·001764\ (t' - 212)}{1·37494} + ·847$$

$$= ·847 + \frac{·000882\ (t' - 212)}{1·37494}$$

But $h = (t' - 212)\, s\, c$, which by substituting the value of s becomes

$$h = \left\{ ·847\ (t' - 212) + \frac{·000882\ (t' - 212)^2}{·137494} \right\} c$$

Now the addition to the volume of steam produced by heating it from 212° to $t' = v - 100 = \dfrac{·2083\ (t' - 212)}{1·37494}$ and the water in an equal volume, may be found by this proportion

$$100 : b : : \frac{·2083\ (t' - 212)}{1·37494} : \frac{·002083\ (t' - 212)\ b}{1·37494}$$

= weight of water in a quantity of steam, whose volume at 212° is $v - 100$. Hence, supposing the latent heat of steam to be 1000° we have

$$h = (1000 + 150)\, c \times \frac{·002083\ (t' - 212)}{1·37494} = \frac{2·3954\ (t' - 212)}{1·37494}\, c$$

Now since h = heat required to produce an additional volume of steam equal to $v - 100$ by heating the steam out of contact with water, and since h' = the heat required to make the same addition to the volume of the steam by generating it from water, it follows that the saving of heat by using the former method is $h' - h$

$$= \frac{2·3954\ (t' - 212)\ c}{1·37494} - \left\{ .847\ (t' - 212) + \frac{·000882\ (t'\ 212)^2}{1·37494} \right\} c$$

which reduced $= \dfrac{1·2308\ (t' - 212) - ·000882\ (t' - 212)^2\ c.}{1·37494}$

The weight of water in steam equal in volume to v at 212° is evidently $b\,\dfrac{v}{100}$ consequently the heat required to generate from water steam equal in volume to v, is $b\,\dfrac{v}{100} \cdot \dfrac{1150\,c}{b}$ which by substituting the value of b becomes $1150\left(1 + \dfrac{·002083\ (t' - 212)}{1·37494}\right) c$

And this being reduced gives the whole heat required to raise steam equal in volume to v from water

$$= \frac{1581·181 + 2·3954\ (t' - 212)}{1.37494}\, c$$

consequently by this formula the heat saved is expressed in parts of the whole heat used in generating steam in the usual way

$$h' - h \cdot \frac{1·37494}{1581·181 + 2·3954\ (t' - 212)} \cdot \frac{1}{c}$$ by substituting this becomes

$$\frac{1·2308\ (t' - 212) - ·000882\ (t' - 212)^2}{1581·181 \times 2·3954\ (t' - 212)}$$

If the steam be heated to 600° then t' = 600°, and the formula in such case gives the saving equal to about $\frac{1}{7}$th of the whole fuel used. Our former mode of determination gave the saving at $\frac{1}{7\frac{1}{2}}$, or $\frac{1}{7}$ very nearly. The minute difference arises from the specific heat having been in the one case supposed to be uniform, and in the other to vary inversely as the specific gravity.

SEWERS OF THE METROPOLIS.

To the Worshipful Her Majesty's Justices and Commissioners of Sewers for Holborn and Finsbury Divisions.

[In the last month's *Journal* we offered some observations on the construction of sewers, and reserved the examination of other portions of Mr. Donaldson's address and Mr. Chadwick's report for another occasion. Since writing those observations, we have had put into our hands a very able report drawn up by Mr. Roe, the surveyor to the Holborn and Finsbury divisions of sewers. As this report so fully enters into the subject of "flashing," we abstain from offering any remarks of our own, but leave it in the hands of Mr. Roe, whose experience on the subject, enables him to report upon it far better than we could have done had we attempted it: by a reference to the engraving of Mr. Roe's flushing apparatus, given in the last September number of the *Journal*, Mr. Roe's report will be better understood, and to all those of our professional readers who may take a deep interest in the question, we strongly recommend them to inspect the apparatus fixed in the sewer of Hatton Garden, opposite the office of the Commissioners of Sewers of the Holborn and Finsbury divisions, by an application to the Clerk of the Commissioners, we feel assured that any member of the profession will meet with the same courtesy that we did, and obtain permission to inspect the apparatus.

At the Court, held October, 1842, an order was made "that the surveyor prepare and lay before the next court, a Report as to the result of the use of flushing apparatus for cleansing sewers, with an account of the expense incurred, and probable saving to the Commission, and embracing the general improvements in drainage that have been adopted by this Commission." The surveyor, in obedience to that order, has prepared a report, which he begs respectfully to lay before you.

Several honourable Commissioners at the last court having expressed a desire that the surveyor should give as full explanation as possible of the method of flushing, and as to what effect it would have upon sewers having little or no fall in them, and upon private drains, it seems necessary to enter into some detail of the cause of flushing being suggested from the necessity that exists for using some artificial method to clear large portions of the sewers from the foul deposit that accumulates in them.

The Holborn and Finsbury divisions are peculiarly situate as having no immediate connexion with the River Thames as an outlet, the waters from these divisions having to pass through one or other of the adjoining districts of the city, the Tower Hamlets or Westminster, before reaching the river. The sewage of the Holborn and Finsbury divisions has therefore of necessity been formed to such outlets as the other districts presented for use, and these formerly being put in without a due regard to an extended drainage, the sewers of your Commission have not had the benefit of the best fall that could have been afforded to them. Of late years, the adjoining districts have lowered many of their outlets; but to alter the existing sewers of your Commission to the amended level, would require the rebuilding of about 323.766 feet of sewer, at an expense of about £200,000, exclusive of the cost of connecting sewers where the cutting would be deep, and of connecting existing surface and house drainage with them, which would make the total amount of cost nearly a quarter of a million. Still, as the lowering of those outlets has taken place, you have availed yourselves of them to a considerable extent; witness the line of sewer to Holloway, the City Road line, the Goswell-street and Golden-lane lines, and several others, varying in length from one to four miles.

The city, some time since, sent to ask you, as data for the improvement of their sewage, the depth of sewage which it would be desirable ultimately to obtain at the junction of their district with yours;—your answer was, "the greatest depth that can be obtained." In lowering their outlets, the city have accordingly afforded the greatest depth they could; the Tower Hamlets express their intention to do the same. The covered portion of the Holborn and Finsbury divisions appears to be greater than any other district north of the Thames, the return of houses rated to the sewer rate in 1833, as made to the House of Commons, showing an excess of 723 houses above the Westminster district.

In the Holborn and Finsbury divisions there are about 98½ miles of covered sewers for house drainage, exclusive of several miles in length built by individuals, previous to the present regulations being made: there is also about 18½ miles of sewage for the surface drainage, and about 10 miles of open sewers.

In a large proportion of the covered sewers from various causes, accumulations of foul deposit obtain. These accumulations existing beneath the streets in a state of ferment for many years, were a cause of much disagreeable and unhealthy effluvia, and were a further annoyance to the public by choking up the private drains when they attained to any considerable quantity. The remedy for the evil, when complained of, was only to be had by raising the noisome substance in pails to the level of the street, and carting it away; a process which, in itself, was subject to many manifest objections, and made the breaking up of the pavement and roads, and the consequent obstruction of public thoroughfares, unavoidable.

On a general examination into the causes of deposit, one thing that arrested attention was this, viz. that in sewers of the same form and with the same fall or inclination, a different degree of accumulation was found to exist. In some instances this difference was occasioned by the common run of water being greater in quantity in one sewer than another. In other sewers the current of water coming in, where old sewers improperly met at right angles, was found to cause, at the junction of the two streams, an obstruction to the flow along the main line, and here deposit accumulated; and where the collateral sewers were connected with the main line at right angles and at different levels, the obstruction was still greater: for example, in one instance where the collateral sewer was 3 feet above the level of the main line, a deposit was formed of a foot in depth, extending in a shoal up the stream to the length of several hundred feet from the point of junction, while below that point the sewer was perfectly clear. It was also observed, that where a gully neck delivered the surface water of the street or road into the sewer through the crown of the arch, an obstruction was caused in the sewer and deposit accumulated largely on the up-stream side. The whole of these obstructions tended to lessen the capacity of the main line of sewer. The inequality of the bottom of many sewers, and the little fall in others, were causes of accumulation of deposit, and the common run of water in many sewers was found to be insufficient to carry the deposit away.

To remove accumulations from the sewers in a way less offensive than the prevalent mode, to construct the sewers on such principles as were likely to lessen the cause of the formation of deposit, became subjects of consideration. Levels were taken through the Holborn and Finsbury divisions, to ascertain the practicability and expense of remodelling the sewers and rebuilding them at the lowest level which the outlets would afford; but it was found that the level was such as would not give that fall to the sewers as would secure the passing off of the foul matter with the common run of water, and that the utmost that could be obtained would be the natural cleansing of one-half of the sewers, while the remaining portion would still require artificial aid. The cost of lowering the sewers to obtain this partial relief would be, as before stated, nearly a quarter of a million sterling.

This result the surveyor communicated to Mr. Donaldson, the chairman of the Westminster Commission, who, on examining in July 1840, the flushing apparatus now in use, agreed that it would do well for old sewers, but expressed a desire that all new sewers should have such a fall as not to need flushing.

There being a current of water of greater or less quantity in all sewers, in some constant, in others periodical, the idea presented itself of turning this ordinary current to advantage in preventing the accumulation of deposit; and to do so, the use of dams at certain distances asunder, to collect heads of water, was thought of.

A series of experiments was commenced in order to ascertain what velocity could be obtained, and how far such flushes of water would maintain velocity sufficient for the purpose required. These experiments were made with board dams fixed in the sewers, and the results led to the conviction that the deposit might be removed at less expense by this than by the prevalent method. In making experiments it was observed that the effect was the greatest when the dam was removed the quickest. Sufficient data having been acquired, the matter was laid before you, and a great number of openings were directed by the Board to be made in various sewers having different degrees of accumulation, that you might personally see the effect of the plan on an extended scale. The result proving satisfactory, you encouraged the idea, and several of your body made very valuable suggestions upon the various methods of application which were brought before you; and a report was directed to be made upon the system of flushing, and on other suggested improvements which you were pleased to adopt. In that report it was stated that the average yearly cost of cleansing was about 900*l*. per annum. To this there would in future have to be added the cost of cleansing such sewers as had not then been cleansed, but in which deposit was accumulating, and in time would need removal. An example of this class of sewers may be seen in the extensive sewage on the Whiskin estate, Clerkenwell. These sewers have been built about twenty years, and have not required cleansing until this winter. The different degrees of accumulation in these sewers show also many of the causes of accumulation where sewers are well built and have a good fall in them. For instance, the sewer in Meredith Street having a constant flow of water turned through it from St. John Street Road is kept free from deposit, whilst in the sewers in Whiskin Street, Skinner Street, Coburg Street, and the upper part of Gloster Street, the common run of water being too small to keep them clear, deposit accumulates; and in the lower part of Gloster Street, where the junction with Meredith Street was at right angles, the deposit had accumulated to nearly twice the depth that it had done in the other sewers. Of this class of sewers that would gradually come under the necessity of cleansing, there is about 97,498 feet, which, estimated at the quantity of deposit contained in the above named sewers, would, by the old method of cleansing, involve an expense of 244*l*. per annum, in addition to the sum before named.

In the Report before named, it was stated that if the average sum which the cleansing then cost was applied for seven years, and the cleansing done by flushing, the apparatus and side entrances might be fixed to the sewers without any extra charge whatever, and the public would, at the end of that period, derive the benefit of a saving of nearly 800*l*. per annum, besides securing, during those years and for the future, a saving of 300*l*. per annum in the item of cleansing, which the Commissioners had effected under their then existing contracts. The flushing system being adopted by you, the method of carrying it out was ordered to be as follows, viz. that when a sewer was complained of and required cleansing, the foul deposit should be flushed away, and apparatus fixed to enable it to be kept free from accumulations of deposit in future. The result to this time is as follows. Since the commencement of the system of flushing, the foul deposit has been washed away from about 16 miles in length of old sewers, on which have been placed 59 side entrances and 67 flushing gates. After deducting from the cost of removing this deposit by the old method, the expense of all the side entrances and flushing gates, there remains a saving of 445*l*. 13*s*. 6*d*., and the side entrances and apparatus are furnished for future use. These sewers are about 2-7ths of those that appear to have deposit accumulate in them; and 2-7ths of the average annual cost of cleansing by the old method would be 326*l*. 17*s*, The annual cost for men to work these gates is 106*l*., forming a saving of 220*l*. per annum on these 2-7ths of the sewers. The total cost of flushing apparatus to these 2-7ths of the length of the sewers has been 434*l*. thus whenever that apparatus should require renewing, the amount of two years' saving will renew the whole. It is not likely they will require renewing for between 30 and 40 years, if then. It is very probable that the interest of the saving will keep the apparatus renewed. There is also the saving to individuals of the cost of cleansing private drains, which, by the system of flushing, can never become choked by accumulations in the sewers as heretofore; and when it is considered that many sewers required cleansing every fifth year, the amount of expense and annoyance must have been considerable. Another benefit has been the avoidance of breaking up the pavement and roads, the cost of replacing which for holes that must have been made to cleanse the sewers that have been flushed, would have been 370*l*. The raising large quantities of foul deposit to the surface, to the annoyance of the inhabitants and passengers, has been prevented. And the side entrances and flushing where they occur have afforded facilities for the men to rake the deposit from old gullyholes into the sewers, from whence it is washed away, thus preventing the breaking up the paving round the gullyholes, and a saving in the article of cartage of the deposit. In one year and a half the saving from this cause in the amount paid for reinstating paving round the gullyholes alone has been 101*l*. 8*s*. 4*d*. A misconception appears to exist that each flushing gate requires a man to look after it; it may not therefore be irrelevant in this place to state that one man will be able to look after and manage all the flushing gates that may be placed in a district containing 15 miles of sewer.

With respect to private drains, the flushing gates are placed on such a principle that, if the whole of them were shut for twelve months together, the houses draining into the sewers would not be at all affected by the water in the sewers; but these gates are never shut except periodically to collect a head of water, and after the head is let off the gate is fastened back, so that no obstruction whatever is caused any where by the application of the system of flushing. At present, as above stated, the flushing gates are placed in such a manner that if kept shut for months together, the water would not enter the private drains; but the result of experiments made upon this point was such as induces the surveyor to state it as a matter worthy future consideration.

Several houses by the side of the open part of the River Fleet at Kentish Town, have drains from their privies emptying into the sewers; these drains were nearly filled with privy soil, which exuded and presented a most filthy spectacle along the side of the open sewer. A wooden flushing gate was constructed to pen up the water which rose gradually to such height as to completely fill the drains. The gate being very large, was made to open suddenly, by the simple principle on which the drag chain of a wagon is loosened. When the head was up the gate was opened, and the water rushed away. The effect upon the drains was, that the sudden withdrawal of the water brought out with it, the soil with which they were nearly filled, and left them in as clean a state as they were when first built. It also drew away all the soil and filth from the open sewer, as far as the head of water extended. Since the flushing gates have been fixed, particular notice has been taken what the effect is upon neighbouring districts, through which the waters of these divisions pass before they reach the Thames. The depth of the deposit was measured at every hundred feet length before using the gate; in one instance the length measured was 2440 feet before reaching the main outlet to the river. The gate was then shut, and a head 2 ft. 6 in. in height obtained, containing about 208 hogsheads of water; this head was let off, and then the whole length of sewer was again examined, when it was found that the deposit had been washed away in the whole length. In another instance the head of water was 3 ft. in height; and this was found to wash deposit away for the whole length of 3250 feet, that being the length from the gate to the main outlet. The total length of continuous sewer that a head of water at one flushing gate would serve to keep free from accumulations, has not yet been ascertained, the greatest length by experiment being 3250 feet, as just stated; but from the velocity of the current when it reached the extreme end, and the depth of water the head furnished at that point, the surveyor has not the slightest doubt but that more than a mile in length of continuous sewer might be kept clear by the use of one flushing gate.

But the washing away below the gate is not the only benefit derived from heading up water by flushing gates, for the effect which took place, in the manner named in the private drains at Kentish Town, is also beneficially felt at the heads of sewers, and in other situations. The drains from the houses in Eagle Street, Red Lion Square, enter the sewer near the bottom, so that this sewer has required cleansing as often as twice in five years, the depth of deposit being one foot and upwards; this sewer is nearly on a dead level for 300 feet. There is a flushing gate placed so as to head up water in this sewer to a height of one foot eight inches, so that when there was 11 inches of deposit, there was nine inches of water standing over the soil. The head of water was let off, and it was found that an average of 3½ inches in depth of deposit had been drawn away with the water from 300 feet of sewer by this one head.

The accumulation of deposit in this sewer is prevented by this process, which occupies a man rather less than one day in the year. The East Long Alley, and part of the Moor's Alley sewer, have bottoms of the most irregular description; the cleansing the deposit from these formerly cost on an average 16*l.* per annum: the accumulations are now kept down by a flushing gate of three feet in height, penning up the common run of water; to work which, occupies a man rather less than three days in the year.

The open sewer at the back of Glo'ster Street, Hoxton, was formerly so offensive in the summer season, that one of the inhabitants, from that cause only, petitioned for leave to arch over, at his own expense, the portion opposite his premises, which was accordingly done. But since you have placed a flushing gate in the covered sewer which empties into this open sewer, the use of that gate has not only kept down the accumulations in the covered sewer, but has had the effect of keeping the open sewer in question clear for its length of several hundred feet, thus preventing the dangerous nuisance which formerly existed. The saving in this instance is greater than that named as effected in the East Long Alley sewer.

In regard to the effects of flushing the deposit into the river Thames, the surveyor has made observations, and taken measurements, which enable him to arrive at the conclusion, that rather more than 14-15ths of the soil and impurities that entered the sewers in the Holborn and Finsbury divisions, was washed to the Thames by occasional rains, and the common run of water in the sewers.

That much road drift is swept through the gully grates into the sewers is certain. In Bedford Place, which has been lately flushed, the depth of deposit was nearly four feet; and amongst this was found a layer of road drift in one part, nine inches in thickness.

In concluding this portion of the report, it may be in general observed, that if there be running through a sewer, a sufficient body of water with sufficient velocity to prevent deposits, *that*, of course, is the best arrangement. But such an arrangement can only be obtained in main lines of sewers, unless a considerable expense be incurred in the purchase of water; and this expense would far exceed the expense of cleansing by flushing. But where there is not a run of water of sufficient body to keep the sewers clear, there is, and must be, a deposit.

A convincing proof of this appears in the sewer, in a part of Holborn, which is in the Westminster district, and which is connected with the Essex Street sewer, which has been lowered from its outfall at the Thames into Holborn, and thence along Museum Street, Bloomsbury, to the boundary of that district; to which point it was completed in 1839. Yet with the advantage of a connexion with a sewer lowered from the Thames, and at a point very little more than a mile from the river, this part of the Holborn sewer has a considerable accumulation of deposit in it.

The New River Company expressed their willingness to supply water at certain seasons at a moderate expense to your Commission, where it might be needed for flushing; but at present, the common run of water, by being penned up at intervals, has been found sufficient for the purpose. The use of flushing gates, supplies the want of a sufficient fall in the sewers, and also the want of a continuous and sufficient flow of water at a much less expense than the cost of the prevalent filthy method of clearing the sewers from accumulations of deposit.

Where there is not a sufficient fall and flow of water, then by damming up the common run of water and letting it off suddenly, an artificial fall of the water is obtained, which answers the purpose. The ordinary fall at which it is required that sewers shall be put in at, is about 5½ feet for the half mile; there are, however, cases where such a fall cannot be got: it is found at Eton, for example, that a fall cannot be got of more than two feet in half a mile, and in parts of Hamburgh not even of half that height. Under such circumstances, unless there be a large body of water, with an adequate flow, there must be a deposit. It is in such cases that the flushing apparatus, collecting the common run of water supplies a remedy. If a continuous line of sewer were formed on a dead level, and if the water be raised by a dam 5½ feet, then when the water is discharged, it has the effect of sweeping away silt, or of keeping half a mile of continuous sewer clear from deposit, producing the same effect as a fall of 5½ feet in the half mile with a continuous flow of water.

When the surveyor first suggested the present method of application to the principle of flushing, he asked your permission to take out a patent for it; but your opinion being that it should be left open for the use of any who might wish to adopt it, he did not proceed therein; as from its promising to prove a saving of considerable amount to the public at large, you as a public body did not wish a monopoly to be made of it; and in accordance with this spirit other Commissions of sewers were invited to inspect it.

Many persons, interested in sewage, have looked at the flushing apparatus used in these divisions, and the surveyor being desirous of the best possible plan, has always expressed his wish that any one would suggest anything that might answer the purpose better, but as yet he has not been favoured with any suggestion on the subject. Much approbation was expressed by many, and one surveyor of sewers considered it clever; Mr. Lindley, who is employed to lay out the new sewage for Hamburgh, expressed his high satisfaction with the plan, and at the clean state in which the sewers are kept by its use; and considered the curved junctions as an excellent engineering work; and the form of your gullies and shoots the one that should be generally used. Captain Vetch, who has been employed to lay out a plan of sewage for Leeds, suggests flushing for general use, and expresses his intention of using all the improvements you have adopted, in every place where he has any influence.

It is interesting to find that the principle of flushing has been in constant practice for 400 years at Eton College, during which long period the sewers have been kept free from accumulations of deposit by its use.[1] Sluice boards are used to keep up a head of water; these are drawn up with a windlass, but the form of flushing gates used by you is about to be adopted at Eton.

In a communication, from a gentleman, the surveyor sent to France to examine the sewers there, it is stated that there are in Paris about 90 miles in length of covered sewers, the whole of which are constantly and regularly flushed by the use of wooden dams, employing upwards of 80 persons. These flushings with wooden dams, do not, however, clear the bottoms of the sewers from a heavy black deposit which is therefore scraped together, and got by hand to the main line of sewer, where a sufficient head of water is obtained to wash it away. Now, if the method of flushing used in the Holborn and Finsbury divisions was adopted in Paris, six men would be sufficient to manage the whole of the gates; and from the very superior effect obtained by the method you use, the whole of the deposit in every sewer would be washed away without the labour at present used.

The Surrey and Kent Commission have, I am informed, used side entrances to some of their sewers for years; these were covered by a stone, but since, Mr. Ianson, one of the surveyors to that Commission, has seen the safety grating used in your divisions, he has introduced them for the use of their side entrances, and, I believe, one or both of the other surveyors to that Commission have done the same.

---

[1] The same principle, upon a large scale, has also been in use for many years for scouring harbours and removing bars, as may be seen at Dover, Ramsgate, &c.—Ed.

Another improvement that you have adopted, is a form of gully hole and shoot, constructed with radiated bricks, the shoot being half a brick in substance. The form of these is such as to deliver the water and deposit from the surface of the streets into the sewer, in such a direction as to cause no obstruction to the flow of water along the sewer.

There have been 690 gullyholes and 13,060 feet of shoot built after this improved manner; the saving in expense is £2149 11*s.* 9*d.*

An improved form of grate was also adopted, by the use of which there has been a saving of £422 12*s.* 6*d.* effected.

The adoption of the present method of cleansing the gullyholes, introduced in the old system, has effected a saving of £200 3*s.* 2*d.*

By the improvement in the form and construction of new sewers, a saving of £1094 6*s.* 6*d.* has been effected on 14,591 feet length of sewer. In no case has the curved form of sewer failed; nor were there any struts at all in the new sewer lately built from near Thornhill Bridge to the Model Prison; nor any left in, as none were required.

Every engineer and scientific person must agree that curved work for sewers is stronger than upright walls, where the substance of material is equal. By the use of curved work, you have been enabled to adopt a sewer for the use of short streets, by which a saving of nearly 5*s.* per foot lineal is effected from the cost of your second size sewer, which, when the great length of sewers required in situations where this sewer will suit, is considered, the item of saving will be found ultimately to reach a very considerable amount.

Of the benefit of curved junctions and proper curves to turns in sewers, it would seem needless to utter one word; and whether it be better for water conduits to have turns with curves, or turns with angles, it could scarcely be expected that there would be two opinions; and in sewers where the water is loaded with foul matter, surely the less obstruction there is to the current the better. Besides, curved junctions are in reality a saving of expense to the public, by preventing occasions of obstruction where deposit would otherwise accumulate.

To illustrate this, take the capital letter T, the head of the T to represent two sewers, the currents of water in which meet at the point where the upright portion of the T touches the head thereof, and then flow down in the direction represented by the stem or upright of the T: this seems bad enough; but a little way along the left portion of the head of the T let another line be drawn perpendicular thereto: this will represent a sewer coming in at right angles with a considerable flow of water, adding to the obstruction formed by the meeting of the other two streams, it being only six feet from that adverse junction: and the natural consequence is, that a very considerable accumulation of deposit has taken place. And if two other lines be drawn across the last perpendicular line, each of those lines will represent two sewers coming into that main line at right angles and opposite to each other, so that the water falling from the sewer or the highest level not only meets and obstructs the current of water in the main sewer, but presents an obstacle to the flow of water from its opposite neighbour, hence considerable deposit has formed in the latter; such consequences accruing from junctions at angles, entail a perpetual expense upon the public in the removal of deposit.

The above is a description of part of a new line of sewer and its junctions, built within the last seven years.

The next improvement which the surveyor has to report upon is, the adoption of side entrances to new sewers in lieu of man-holes or apertures, as formerly used. In the 24,624 feet of new sewer built by your Commission, since this improvement was adopted, side entrances, and such flushing gates as was deemed necessary, have been placed in lieu of apertures, and the saving by so doing has been £1349 11*s.* In the 21,048 ft. of sewer, petitioned for and built by individuals after the same manner, a saving to them of £782 has been effected, after allowing 25 per cent as their profit, or the amount which a builder might think he could save by doing his own work, instead of paying for it at your contract prices. The avoiding breaking up the pavement or roads, and other advantages which the use of side entrances secures, the surveyor named in his former report on this subject.

The total saving by the adoption of flushing apparatus, and of the other improvements named in this report, in about two years, is £6443 19*s.*; and 2-7ths of the sewers that require artificial aid in removing deposit are provided with side entrances and flushing apparatus for future use.

On the whole, the amount of immediate saving which it was calculated would be effected by your adoption of the improvements herein named has been exceeded; and this will be the case with the perpetual annual saving; experience showing that by flushing sewers with water, a saving of nearly two-thirds may be made from the cost of the old method of removing deposit. But the fact which is of more importance, in a sanitary point of view, than the expense of removal is, that instead of the two or three thousand tons of refuse, which may be removed for £1000 or £1200 per annum, remaining for years decomposing in the sewers, and generating miasma which penetrates the houses and creates disease there, and escapes, and is diffused in the streets amongst the passengers, the deposit would by the flushing apparatus be removed, with sufficient rapidity to prevent any extensive decomposition or any smell.

The men engaged in cleansing the sewers have a more healthy employment; the laying out of large quantities of foul accumulations on the surface of the streets, which was formerly the practice, is avoided; the pavements of the streets are undisturbed: the putting in drains surreptitiously is easily detected; private individuals are saved from the annoyance of having their drains choked, and the expense of cleansing them in consequence; and these are considerations of future expenditure in sewers, which your systematic adoption of these and other improvements will influence, so as to render your having done so one of those circumstances, the great and beneficial consequences of which will be felt, not only in these kingdoms but in every civilized nation in the earth.

In conclusion, I respectfully beg permission to make a few observations upon the address of the Chairman of the Westminster Commission, lately published and circulated, in consequence of the late sanitary report of the Poor Law Commissioners. At page 30, there is a paragraph, as follows—"The truth is evident, that the Secretary of the Poor Law Commissioners has been content to inform himself, in respect of the Metropolitan Sewage, by special deference to the opinion of one individual, whose object has been to give himself importance, by vaunting his own contrivances, by exalting his own Commission, exaggerating his own success, and with unbecoming boldness casting unjust reflections on the adjoining Commissions, traducing the competency of his brother surveyors of the surrounding jurisdictions."

In the first place, I beg to state that the first communication I had with the Secretary of the Poor Law Commissioners, on this subject, was his sending to me to give information as to sewerage, his questions being founded upon a printed copy of my report to your court, in April, 1840; the only information I gave him appears in the Report, at page 373, to part of page 378, and a quotation at page 61, on the quantity of deposit passing from the sewers to the Thames.

I never endeavoured to show the superiority of the regulations of this Commission, by comparing them with those of other Commissions: and in the few observations I made as to the methods adopted in the neighbouring districts, I endeavoured to show that improvements were in progress.

After my interview with Mr. Chadwick, I informed the surveyor of the Westminster sewers that I had been examined, and expected he would be sent for. Finding from a letter of Mr. Kelsey, the surveyor of the City sewers, that his feelings were much hurt, and that he attributed much of the Secretary's blame to me, I wrote to him, and he sent me an answer, from which the following is an extract.

"Dear Sir,

"Did my letter to the Poor Law Secretary produce no other result than your communication, I should feel highly gratified, for it has entirely disabused my mind of an impression which is by no means confined to myself.

"With your leave, I will show your letter to a gentleman, whose father is connected with another Commission of sewers, for it is well that the ill impression should be counteracted.

"It is much to be regretted that the course which you supposed would be taken was not taken,[2] but advocates of any particular system never want to know the whole truth, but only just as much as can be bent to suit their object."

And I have been informed that Mr. Dowley, the surveyor to the Westminster Commission, never considered that anything personal to him or others was meant by me at all.

In answering the questions of the Poor Law Commissioners' Secretary, I cast no reflection or said one word on the competency of any one: and it is mere assumption to say that Mr. Chadwick has been content to inform himself, in respect to metropolitan sewerage, from me only, when the many quotations he brings from others show the contrary.

As to exalting my own Commission, it needs not my feeble praise; its own acts—the scientific knowledge of its members—the attention given to every sort of improvement, will ever produce for it that meed of praise in the public mind which is justly due. I have always been ready to give every information in my power to anyone that asks for it: but, that little is rightly known of what is doing in this Commission, or how it is done, is very evident; a fact, which the Report I this day have the honour to lay before you, will confirm.

I have the honour to remain,
Gentlemen,
Your obedient and faithful servant,

Jan. 27th, 1843. John Roe.

---

2 That of other surveyors of sewers being examined.

NOTES ON EARTH WORK, EXCAVATION, CUTTING, AND FORMING EMBANKMENT UPON RAILWAYS.

Article V.—Tenders, Schedules, and Securities.

The preceding paper treated on the supervision of works during their progress; in the present one I will endeavour to give a sketch of the custom prevailing amongst the various railway works, previous to the actual commencement of works, in the prior operation of advertising the works for competition, and the condition and manner of taking securities. In the general form of contracts, plans, sections and specifications are exhibited, and printed forms of tender, drafts of contracts, and printed schedules are distributed to intending competitors; in some few cases the approximate quantities of the principal works, as earthwork and masonry are given, but the contractor has to satisfy himself both as to quantity and nature of the ground, the companies furnishing him with sections of the strata from actual borings. The directors do not bind themselves to accept the lowest tender, but reserve to themselves the power of accepting any offer which they may think fit. The successful party has to enter into a bond with two securities to the extent of 10 per cent. on the amount of contract. The amount of contract is generally exclusive of permanent way, which is let separately, as also the keeping of the works in repair for twelve months after completion. As regards the permanent way, the Company furnish the material, and the contract is taken only for laying, and perhaps including keys, wooden pins, or small wares. The keeping the roadway in repair has been tendered for by contractors at sometimes six times the amount that the actual cost has been to them. After experience has tested the amount, it has produced a feeling amongst engineers that it is not expedient to include in the contract the keeping the works in repair, but the contract to be ended on the certificate of completion being obtained from the engineer. When the directors meet to receive tenders, it is expected the parties tendering, or an authorized person on their behalf, will attend. The directors make no allowance to the unsuccessful competitors for the expense of their estimates. In some cases the bondsmen of the contractor are bound in a specific amount proportionate to the estimated amount of the contract by the engineer, not a per centage. The time of completion is in some cases stipulated, and a penalty imposed if the works be not completed within the given time, in an increasing ratio, say 100*l.* for the 1st week, 200*l.* for the 2nd week, 300*l.* for the 3rd week, and increasing by 100*l.* per week for each successive week.

The design and responsibility of centreing for bridges, &c. and the onus for the execution of the works are thrown upon the contractor, he is to repair all injuries, from whatever cause, during the execution of the work; he is not to be allowed any day bill for work "expressed or implied" by the specification, and the decision of the engineer is to be final and binding upon the contractor, in all cases where there shall be any dispute or misunderstanding regarding the specification and drawings; and should an insufficient number of men be employed, the engineer is to have full power to take the whole of the works out of the hands of the contractor, seize upon his plant, and cause the work to be finished by any other person. The payments on account are regulated by the certificate of the engineer, and a per centage retained in hand varying from 10 to 20 per cent. Some altercation amongst parties has arisen in their not being allowed to draw for material on the ground and not being in the work. The contractor is made responsible for all damage that may be done to adjoining lands, and for any penalties and forfeitures imposed by the Act of Incorporation as regards crossing canals or public highways. He, the contractor, is to furnish tools and assistants to the engineer in setting out the works, and the engineer has power to remove all materials insufficient as regards the quality at his mere dictum.

I think, as a matter of justice, that the lowest tender should have the contract, provided he obtains the stipulated securities; if the tender be not accepted, the party ought to be paid for his estimate. I consider that the present mode of taking security is unfair and inefficient, and that if penalties are to be exacted for delays, that an equivalent bonus should be given to the contractor for any number of weeks that the works may be completed before the stipulated time. I have, I believe, read attentively all the works in the English language relative to railways, and do not think that this important subject has been treated on by any party, even in the splendidly got up works of Mr. Weale, which merely give the specifications of the quality of materials and mode of execution of the works without note or comment. The practice of London for tenders of buildings under an architect is, that when a work is to be tendered for, the architect appoints a surveyor, and a limited number of contractors of note and reputation are written to, and they appoint another surveyor, who, with the former, make out a bill of quantities which is supplied to each competitor, as also the cost of the estimate, which is included in each tender, and is generally $1\frac{1}{2}$ per cent. on the amount, and which is paid by the successful party. The architect charges 5 per cent. if he superintend and carry the work into execution, and if the job fails for want of capital or change of opinion, the architect only gets paid at the rate of $2\frac{1}{2}$ per cent. on the estimated cost.

I cannot forego this opportunity of directing attention to an article in the *Companion to the British Almanac*, page 21, 1843, on the sanatary condition of the people, where Mr. Chadwick observes that "In the execution of other local works, as sewers, roads, and drains to houses, no care is at present taken to ensure the superintendence of persons of competent skill. Noisy parish brawlers obtain appointments of this nature, and are paid at an extravagant rate for inefficient services occupying only a part of their time. A case is mentioned of an illiterate person receiving a salary of 150*l.* a year, or as much as a lieutenant of engineers and a private, or as much as three serjeants of sappers and miners." Mr. Chadwick, with respect to the other works alluded to, states, a hundred thousand pounds have been received in fees for surveys of new buildings per annum, and that "this sum would be sufficient to pay the whole corps of Royal Engineers, or 240 men of science, and the whole corps of sappers and miners, or nearly 1000 trained men." Mr. Chadwick also observes that under the Tithe Commutation and Parochial Assessment Acts, that "amongst the most satisfactory surveys were those executed by a retired serjeant of sappers and miners." In respect to railways, the point of the government wedge is already introduced, and I would warn the assistant engineers to unite boldly against this attempt to interfere with them.

Whilst extracting from the *Companion to the Almanac*, I cannot forego the temptation of extending my extracts to the "Notes on railways," and the new position assumed by them in page 78, alluding to the Norwich and Yarmouth line: "the difficulty in obtaining the capital was so great, that the scheme was all but abandoned, when a new mode was devised whereby the contracts for the whole works were secured to competent parties, on condition of their investing a large portion of their contract prices in the undertaking; in this instance the contracts were taken at the original estimates of the engineer; still the principle thus adopted might obviously lead to a good deal of jobbing, and is so far to be reprehended." In the above observations I perfectly agree, and have made the extract that this *rara avis in terra* may be more fully known through the *Journal*.

Since writing the above, a special meeting of the London and Birmingham Railway Company has been held (Jan. 16), to consider the expediency of applying to Parliament for an act to make a branch railway from the main line at Blisworth to the city of Peterborough. This meeting is reported in the *Railway Times* (Jan. 21), from which I take the following conversation bearing on the subject. A proprietor asks, "Am I to understand that there is to be no specific contract for the completion of the work from end to end, and that the contract will be advertized in the usual way? I presume it will be a common contract." The chairman replies, "In one sense it will be so certainly, but I trust that in another sense it will be an uncommon one, for I hope it will be done within the amount of the estimate. We do not, however, mean to advertise, but to adopt the now usual course of writing to a certain number of first rate contractors, requesting them to send in tenders within a specified time." Proprietor.—"Then there is no actual guarantee on the part of the contractor that the engineer's estimate will not be exceeded." Chairman.—"We certainly are not now in that position, although, as I said before, the engineer's estimate was accompanied by a tender with a full guarantee for the execution of the works within the sum named." Another proprietor is replied to by the chairman, who says, "I think the honourable proprietor may fairly presume that the estimate will not be exceeded by the mode of tender now proposed. The view of the board was that there ought to be a probability of *reduction* in the terms of the tender, rather than the chance of an increase, and it was that consideration which induced us to determine on *competition*, as far as it can be done with safety. As far, therefore, as the execution of the work goes, I consider that we are in a state of perfect security, and that they will be finished within the estimate." In the above conversation we have the results of the most experienced men as capitalists and engineers that the world has produced, and with as much natural talent as perhaps ever will be produced. From which we learn that the London practice as regards contracts for buildings will be applied to railways, and that competition to too great an extent is unsafe, and that the guarantee of the contractor was for the execution within the sum named as the estimate; thereby fixing a maximum amount, and that the difficulty arose in fixing a maximum. No mention is made of a schedule, or power of making deductions by any given scale.

Another plan, letting out works, has been adopted on broken works, that is, where companies have taken works out of the hands of contractors, by allowing other parties to finish them, at a per centage on the expenditure of 7 to 10 per cent., a check being kept on the contractor by the companies in the weekly pay bills. I have also known other public works, as gas works, so carried into execution. This system is also applied to the agents of contractors and extensive commercial works, a salary being fixed, and a per centage being given on the amount of profits made by the concern.

From the number of responsibilities and restrictions laid on contractors, as previously enumerated, one would have thought there would have been no necessity for the remark, that competition had taken place to too great an extent, and was unsafe. Do contractors rely for profits on extras and unsettled amounts? there being many amounts which remain unsettled for 10 years after the completion or opening of several railways already executed, or do they rely on the law's delay? let the cause now in Chancery, of Ranger *versus* the Great Western company furnish the reply. Again, as to securities; are there no bubble companies? and on what has the contractor to rely on for letting his plant fall into their hands? I can only think his protection must be the cash in his pocket, and his being ready for active defence. I have known a poor contractor ruined, by having his works pushed in bad weather, and he was obliged to leave the works without redress. Ready money is Aladdin's lamp, and will quicken even the perception of a Lord Chancellor. In settling disputes of this nature, arbitration is sometimes resorted to by public companies, to avoid the law's delay; and engineers of eminence are called in to settle the disputed accounts. In all contracts between companies and contractors, it would be well to name two parties, all as referees, in case of dispute, to curb the sole controul of impetuous or peevish engineers.

The practice of the Board of Ordnance, is to fill up a printed schedule of prices. Take smiths work, for instance, the items enumerated most likely to be wanted, will extend to a hundred articles, of any pattern that the superintending officer may order, as, articles of wrought iron, materials for day-work or for store, cast iron, exclusive of patterns. The tender is to be "at how much per cent., above or below the prices inserted in the schedule, he is willing to contract for the supplies;" and only one rate of per centage must be named above or below all the prices in the schedule; and he is to make out his bill at these prices, and add to or deduct from the total the per centage, according to his tender. The generality of tenders are below the prices of the honourable board. The contracts are taken for a term of years, determinable at any period after one year, on either party giving three months notice. Bondsmen, with two securities bound jointly and severally, are taken for the performance of the contract. The superintending officer has the controul of materials as to quality, and imperfections of workmanship, number of and efficiency of men employed. The contractor is to furnish daily a list of men, and weekly a statement of daywork, and how employed, and a list of articles, if any, to which the schedule will not apply. The bills are delivered within 10 days after the expiration of the current quarter, and payment made in the course of the subsequent quarter. In this account of the practice of the honourable Board of Ordnance, we have undoubtedly the nucleus of the principle adopted by the different railway companies; but the chief point, the principle of a per centage, has not been adopted, which I think is the safest for all parties, the company and contractor. I have known the practice adopted by a friend of mine, in a public work of great extent; he sent a schedule of prices to parties, and they were to tender at per cent. on the amount of work (the bills being priced by the schedule) at which they would execute the works. In this mode there is no definite quantity fixed, and therefore no addition and deductions as the works progress, and therefore there can be no extras so annoying to all parties concerned; it is more assimilating to measure and value, with the exception, that the scale of prices is fixed before the commencement of the works. There is a custom amongst contractors of pricing the body of their contract, at a different ratio from that of the schedule, in the expectation that there will be more extra works than deductions here; I warn all parties that so doing, is decidedly wrong in principle and unexpedient in practice. To avoid the above practice, the Manchester and Leeds Railway company inserted two schedules in their proposals, the first containing a list at which the tender is computed, the second containing a list of extra works: in each schedule above 100 items were enumerated. A difficulty often also arises in the measurement of works, as to the custom of the country or trade; and in railway works it is generally expressed, that net measurement only will be allowed, and that brickwork is to include all foundations, digging, pumping water, and all punning[1] or ramming back of walls, backing bridges, &c.

I will now proceed to say a few words on plans, sections, specifications, forms of tender, drafts of contracts, schedules of prices, &c. The two first explain themselves, and the draft of contract is in the province of the lawyer. The specification is supplementary and general; the latter applies to all contracts on a line of railway, and in one case was so voluminous as to extend to 20 folio pages containing 61 clauses. The 61st clause was to the following effect, and will define what is meant by general. "The whole of this specification is to be taken and construed according to the true intent and meaning of it, and in case of the construction of any part of it appearing doubtful, the opinion of the engineer as to the intent of any such portion is to be binding upon both parties." The supplementary specification describes the particular works referred to in the general clauses, as for contract No. 1. No. 5 L, or any subdivision of a particular line, say commencing at chain No. 21, in a field shown in the plan near ———, and ending at chain No. 306, shown in the plan situate near ———, being in length about 3 miles, 4 furlongs, 5 chains, 7 yards, or thereabouts. In the specification a table of the gradients is given, and the number of the bridges, with detailed plans of each. The form of tender is as follows:—"To the Committee of ———. I, of ———, do propose to make and complete the work of the portion of ——— Railway, (inclusive or exclusive of the permanent way, as the case may be), from ——— to, ——— according to the plans and specification, within the period and upon the terms and conditions mentioned and contained in the draft contract exhibited, for the sum of £ s. d., and I have, in the schedule hereto annexed, set forth the prices of the different descriptions of work at which the aggregate amount of this tender is computed, and in case this tender shall be accepted, I hereby undertake to execute a contract according to the draft referred to within 14 days from this date, and propose A B and C D as securities for the due performance of such contract." Again, "I hereby offer to execute the whole of the works described in the specification, &c., and in the event of this tender being accepted, I bind myself to enter into a regular contract, and to find satisfactory security for the due performance of the work, and I agree that the value of any addition to or deduction from the amount of the work specified, shall be calculated at the rates stated in the annexed schedule of prices." In the last case, the real estimate of quantities by the engineer was printed in the schedule, with a description of each kind of work attached, and in the case of the Manchester and Leeds Company before alluded to, the amount of security required was stated in the conditions of the contract; it was, therefore, necessary for the parties tendering to add to their tender. "And I do hereby undertake that A B and C D shall, within a fortnight from this date, execute a bond to be prepared by the Company for that purpose, in a penal sum equal in amount to 10 per cent. on the amount of my tender." The Great Western Railway fixed a definite sum for the bondsmen to become security for on each contract, not a per centage; also that the two sureties be bound jointly and severally with the parties tendering.

Notwithstanding the arbitrary powers of engineers, the complex array of law, and the exaction of bonds, they are all found inefficient as regards keeping contracts within a specific sum, or the gross amount of tenders. Can there then be any thing said in addition to show the inutility of contracts on the usual plan.

I should like to see the principle of tendering now in practice by the Board of Ordnance applied to railways, as before alluded to; and if this plan, with the addition of the quantities (as agreed upon by the contractor and engineer, or by their surveyor) were supplied to intending competitors, I think it would tend to simplify the cost of public works, and at the same time make the officers of supervision and of the executive look more lovingly on each other. I have no doubt, should Government execute the Irish railways, some such system will be adopted by the Board of Trade.

I will, in my next, if leisure permit, enter on the principle and construction of earth wagons, which has not, as yet, had the importance bestowed on it that it deserves. In the mean time allow me to subscribe myself, with all respect,

St. Ann's, Newcastle-upon-Tyne. Your's obediently,

O. T.

[1] The cost of punning per cubic yard, is about twopence, or half the cost of excavation.

ROYAL ACADEMY.

Professor Cockerell's Lectures on Architecture.

(From the Athenæum.)

Lecture III.

The chronological table[1] offered to the students was designed to assist their study of the history of architecture, so strongly recommended; it was a sketch capable of great development—the intelligent observation of antiquity was an all-important object with the architect. No consideration could confer more importance and dignity on the art than that it was identified with time—that the architect himself was a part of history, and that the marked works he performs were, by the consent of language, termed monuments. Such a table presented at one view the religious and moral, the political and technical influences which have guided and developed the art. Through the early centuries we trace it as one of the most active engines of civilization; but it is long before we find the table rich with the names of patrons, architects, or works, and then with many voids of tedious centuries between. The dearth of wisdom or wealth in governments, or genius or liberality in the individuals, accounts for the barren ages; as naturally as do the contrary for the fruits of all the muses. They follow each other as natural consequences, as effects from causes. And it is glorious to recognize the coincidence of epochs favourable to art with the most wise-hearted and generous spirits of history.

Under whom were those more remarkable buildings of Egypt raised? It was when Sesostris built his library, and pointed to its destination by the significant and enlightened subscription—Ψυχης ιατρειον—"The health of the soul." When were those bright edifices erected which have ever attracted the traveller to Athens from every part of Europe, and still do so? It was when Pericles could discuss the buildings he designed with a Socrates, a Plato, a Phidias, and an Ictinus—and so, with minor splendour, an Augustus, a Justinian, a Medici, a Louis XIV., a Frederick the Great, a George III., or a King of Bavaria, have known how to illustrate their era; and, however a half-sighted economy has calculated and complained of the cost, history may be defied to prove that states have suffered from these expenses; those wise princes knew how fructifying they were in real commercial benefits; and never wanted the address to silence the item-counting economists. "Do you complain of these expenses?" said Pericles; "I will find the remedy. I myself will defray them, provided you will allow my name to be inscribed upon the walls." He might have added—"You are prompt enough to vote money to carry on an Affghan war, on a pretence, into Sicily, and fill Syracuse with carcases, to your own disgrace and ruin; but these expenses, trifling in the comparison, these becoming ornaments, these productive fructifying decencies of a great state, you grudge."

When Louis's accounts of Versailles were made up, and his Minister of Finance asked what was to be done with them—"Burn them," said the monarch. He knew as well as Necker the secret "that the arts and sciences repay with usury the expenses of the state in providing for their exercise and culture." He knew, too, that they formed not a tithe of those arrogant and unsuccessful wars which he waged with all his neighbours.

But why are the two centuries before our era less fertile in names? because the Roman sword began to supersede the olive branch of Olympia: and why again do they cease after the second century of our era? because the Emperor himself (Hadrian) professed the art, and murdered his rival Apollodorus, the last great architect of Greece. And now, for twelve centuries, they are obscure under the antagonist rules of feudal and ecclesiastical aristocracy, and re-appear only with liberty and the muses.

Again, for himself, the architect lays to heart the care and circumspection due to *lasting monuments*, and the penalty which the absence of these is to inflict on him in the curse

> Of Ripley and his rule;

and for his patrons, his duty to awaken them to the seriousness of these responsibilities, the compromise of national honour and credit in works which are nothing less than state matters; and were so esteemed in Athens by the appointment of a minister, the δεμιΰργος, answerable for their success. He is humiliated in finding that his own design, with the originality of which he had flattered himself, is but a repetition of former essays. Again, in the contemplation of the slowness of invention, and the imitative nature of our species through centuries. The arch and the dome essayed during 1000 years before they assumed the form of the Pantheon or the Bridge of Narni; and 1400 more are required to accomplish a humble imitation in the dome at Florence. That the Egyptian, Greek, and Roman, as if spell-bound, did as their fathers did—that the monuments themselves are but the copies, more or less altered, the successors of a remote ancestry receding into the night of time. Pliny tells us that the temple of Ephesus had been seven times rebuilt. The oldest monuments of Egypt and of Greece, and of our own countries, are composed of fragments of still ones:—

> Vixere fortes ante Agamemnona
> Multi: sed omnes illacrymabiles
> Urgentur ignotique longa
> Nocte, carent quia vate sacro.

[1] See two following pages.

"They had no *artist*, and they died."

But the technical reflections on this table are not less instructive. The struggle of 2600 years with the monolithe;—the influence of fashions in the design, and of slavery in the execution, of works, reducing the cost by at least one quarter;—the lever, the lewis, the trochlea, and every engine employed by modern masons, are recognized in all the oldest buildings of the east; Stonehenge being one of the few buildings which displays the infancy of art;—the inferiority of ancient cities in the distant view as a conglomerate of low buildings, to those of the modern world with towers and campaniles;—the changes which customs induce;—the church-bell, which in the seventh century hardly exceeded one cwt., and terrified Clothaire and his troops under the walls of Orleans; then the delight and boast of communities, and gradually becoming 80 tons in the 19th century at Moscow, enlarging during those centuries the towers and structures for its reception, and altering by degrees the whole face of architecture;—the use of glass, in narrow windows in the first century, a vast improvement on Phengytes, used till then; the manufacture of the civilized only, till the 12th century; then infusing colours with unseen lustre—glazing in part only the domestic windows, which had shutters below until the 17th, and now in one sheet filling the entire sash. Meanwhile, architecture bends to this manufacture, and changes its features and proportions with the phases of its improvement. And, lastly, cast-iron, which within 40 years has discovered capacities which will alter the whole structure of buildings. We may say with the poet—

> Loin d'ici ce discours vulgaire
> Que l'art pour jamais dégénère,
> Que tout s'éclipse, tout finit;
> La nature est inépassable,
> Et le génie infatigable,
> Et le Dieu que la rajeunit.

The principle to be inculcated seems then to be the acceptance and employment of every useful element of our art, and so to engraft new features, and bend it to the march of human improvement, as to be consistent with taste, while it is also to the great end of use. Thus we shall obtain new creations in the art—which a servile imitation refuses.

These are amongst the advantageous reflections which the contemplation of the chronological table will give rise to.

This evening the Professor purposed offering some remarks on the principal monuments of civil architecture amongst the ancients. As the ritual prescribed the forms of sacred architecture, so political and civil institutions prescribed those of civil architecture: where monarchs sway we have their palaces, suited to the temporal governor of the earth: regarded as God's vicegerent while living, and as demi-gods when dead, their mausolea endure through all ages, in the Pyramids, or in the Moles Hadriana; and where these are supported by castes, we have the Labyrinth, the Temple Palace, and the treasury—in republics none of these are found, but the temple, the gymnasium, the theatre, the stoa, the basilica, and public works abound; when states are absolutely commercial, as Tyre or Carthage, nothing remains but their name in history; their architecture seems to have been confined to the perishable Trireme.

The uncertainty of future existence made duration in the present the earliest object of solicitude; monuments in the pyramid or the obelisk are the most remote architectural works which have reached us. In 1732 B.C. Jacob raised a memorial to Rachel, "that is the pillar upon Rachel's grave unto this day." "The kings of Egypt," says Diodorus Siculus, did not think that the fragility of the body deserved a solid habitation; indeed, they regarded their palaces as simple lodgings, in which each successively inhabited; but they considered their tombs as their peculiar habitations, as their fixed and perpetual domicile.

The subject of pyramids would never be mentioned without acknowledgment to the labours of Colonel Vyse, which for princely liberality and English endurance and disinterestedness are unparalleled, as indeed also for their great interest, since on this subject, debated for so many centuries, he has left nothing to desire.

But, to the architect, no monument of antiquity could be more precious than the tomb of Absalom, in the valley of Jehosaphat, which is monolithic (for the most part), or rather cut in the living rock, and exhibits an Ionic temple *in antis* (like Solomon's temple), with a Doric entablature, an Egyptian cornice, and a tholus or circular attic, surmounted with a conical top and a pomegranate; all features in perfect correspondence with the reasonable expectations regarding Jewish architecture, which, however original in *plan* and disposition, would never be so in ornamental style, because the comparative smallness of the nation, the fortunes of individuals limited by law, the agricultural habits of the people, their discouragement of taste, and their position between great and flourishing countries so remarkable for its cultivation as to lend their artists to the Jews, whenever occasion demanded, were all opposed to the invention of any peculiar and original style of architecture.

A beautiful representation of this remarkable tomb had appeared in Roberts' "Holy Land;" there could be no doubt as to its identity, since tradition amongst the Jews on such a point might always be accepted as full and sufficient evidence—its perfect correspondence with holy writ (II Samuel, ch. xviii.) is striking:—"Now Absalom in his lifetime had taken and reared up for himself a pillar, which is in the king's dale: for he said, I have no son to keep my name in remembrance; and he called the pillar after his own name, and it is called unto this day Absalom's place." Wren calls it "the most observable monument of the Tyrian style." "It were to be wished," says he, "some skilful artist would give us the exact dimensions to inches, by which we might have a true idea of the ancient Tyrian manner."

Labyrinths are amongst the earliest and most astonishing of architectural works; they were found in Egypt, Crete, Lemnos, and Tuscany. Herodotus describes them as surpassing in extent and magnificence: the one he describes (Eut. cxlviii.) was composed of 12 courts, having apartments of two kinds, 1500 above the surface of the ground and as many beneath, in which were the tombs of their kings. "No one could enter them," says Diodorus Siculus, "without a guide." Yet Pliny tells us they were not contrived like the ornament commonly called by that name; in that of Lemnos, says he, were 150 columns turned in a lathe, which a child could move; and this is remarkable as evidence of the use of such a machine in the capitals of the Parthenon, which has been always supposed.

The living use of the Labyrinth is left to conjecture; but we may easily conceive their adaptation to a people of castes, with whom they might be colleges for those aristocratic classes surrounding the throne. We are told that all the youth of Egypt, born on the same day with Sesostris, were set apart and educated with the young prince, and thus it was that he found himself surrounded in manhood by attached companions, who carried his conquests and his fame to the greatest height. Where could so vast a generation be educated but in the Labyrinth?

The Professor doubted the interpretation commonly applied to the so called temples of Egypt; he believed them to be rather temple palaces, in which the temporal administration of a great country was carried on, together with the spiritual. The ruins of Karnac covered 10 acres. Within the walls was inclosed a space equal to the whole length of St. James's Street, and four times its width. The comparison of this plan with that of the Louvre and its courts, with the use of which we are familiar (and exhibited with plans of Luxor and Dendera, and Diocletian's palace, and others drawn to the same scale), would show the high improbability of the employment of such vast spaces for the priesthood alone; and it could be shown, especially at Dendera, that all the public business of the realm might be conducted there, and that the Pharaoh himself very probably resided, as in the Arab villages at this day, upon the froad terraces which these vast buildings afforded, raised into the air, and removed from the vermin, inundations, mirage, and confinement, to which the habitations on the soil of Egypt were subject.

The Pharaoh united the offices of monarch and high priest, and all the dignity and imposing awe which the arts could afford, were associated with his presence. The palace was approached through an avenue of sphynxes of a mile in length. The Pylæ were seen afar off raising a vast front of uniform surface, on which were engraved on one side the Pharoah in his warlike attributes reviewing his troops, charging the enemy, whom he annihilates at a stroke, besieging cities; on the other, in his peaceful, administering justice, and the more sacred duties of his priestly office. In front of this were obelisks (the smallest of which is now in Paris), and colossal figures of the Pharaohs.

The first court equals in size Waterloo Place, from the column to Pall Mall. Here, under a colonade, "the King sat in the gate," with "his princes and counsellors;" this was "his porch of judgment," the sculpture and painting of the ceiling symbolized appropriately the passage of the soul through human vicissitudes to a final judgment.

The columnar grove beyond, 325 feet by 266, afforded a waiting hall (the only cool one in Egypt for all the court, so pomponsly described

BEFORE CHRIST.

Note.—The writings of those in capital letters are still extant.

in Daniel: "the princes, the governors, the captains, the judges, the treasurers, the counsellers, the sheriffs, and the rulers of the provinces." Through these was the approach to the Sekos for the god; and on the face of each column of the avenue were represented on one side Osiris, on the other the Pharaoh.

The paving above all this showed a surface prepared for other buildings, apparently of timber: holes occur for the reception of the posts, very large ornamental spouts for the discharge of sewage and water, IN A COUNTRY OF NO RAIN, and therefore only wanted for the uses of a great family. The parapet walls forming the external face of the temple palace, surmounted with the usual cornice, defend and partially conceal these buildings; and at Dendera especially are chapels for the daily services of the Pharaoh and his family on this higher level, and the staircases by which they arrived at them. These were the "*ivory palaces*," the habitations of cedar, and sandel, and almug woods, alluded to in the 45th Psalm, and in which each Pharaoh might indulge his taste, and be "*glad*," and enjoy exemption from the inconveniences of the nether world.

Some very beautiful drawings, by Mr. Jones, representing the actual remains and restorations of the Pilæ, were obligingly exhibited, by permission of that gentleman. An interesting part of the ruins of Karnac was not to be forgotten, namely, a triumphal gate built by Shyshack on his return from Jerusalem, whence he had taken the golden shields put up by Solomon, as described in 1 Kings, xiv.

The treasuries of Atreus, 48 feet in diameter, and the gates of Mycenæ, and the treasury of Orchomenos, of still larger diameter, are the only monuments of Homeric pretension, unless the Lycian remains, discovered by Mr. Fellowes, can be proved to be of that remote period, and that the taste of Sarpedon can be identified by them.

Amongst the objects of civil architecture, few have had more influence on the art than theatres, both in their external elevation, in the application of the orders in relief on the pier and spandrel of the arch, and in the internal elevation, the scene, which has been the occasion of so much caprice and corruption of taste. The theatre, being constantly employed for parliamentary assemblies, required a permanent scene, as well as moveable, and adapted to the performance. It was a subject of vast architectural study and expense. Pliny (lib. xxxvi.) tells us that Caius Antonius silvered the scene; Pretonius gilt it; Quintus Catullus clothed it in ivory. Scaurus surpassed them all; he raised 360 columns, in three ranges: the first was of marble 38 feet high, the next was in glass, the third of wood gilt. Three thousand bronze statues ornamented the intercolumniations. Curion, unable to surpass Scaurus, built two theatres of wood, which, being back to back, could be turned so as to form an amphitheatre for gladiators, displaying the skill of the Roman carpenters to great advantage.

Vitruvius (lib. vii. c. 5.) lamenting the depravation of taste, tells us that Apaturius of Alabanda offered a design for a scene of two stories, the upper called Episcenius, filled with every caprice, centaurs did the office of columns, pediments were twisted in a variety of shapes; all which pleased the people of Tralles, for whom it was designed; but Licinius a mathematician, exposed its absurdity, and it was accordingly reformed on better principles.

The scene of Laodicea (amongst many which the Professor exhibited) was the most extensive, being no less than 254 feet in length. The theatre of Orange, lately published by M. Caristie, was a valuable addition to our information on the Roman scene.

Palladio's scene of the theatre at Vicenza gives the best idea of its feature of ancient architectural magnificence.

Originally of wood, and continuing so for many centuries, it was not until the third century before our era (232 B.C., the theatre at Epidaurus,) that they were built in stone and marble. The Greek theatre approached the amphitheatre, and was a horse-shoe comprising 200° or more, because the orchestra was reserved also for the performance; but the Roman theatre did not exceed 180°, because the orchestra was occupied by the senators.

The Odeum was a covered theatre, chiefly for music; that of Herodes Atticus, at Athens, was the most magnificent in Greece, and had a roof of cedar. The space covered was 240 feet by 159. The construction of such a roof, without obstructing sight or hearing, or injuring external architecture, offers a problem to the architect of no easy solution, and is one of great interest in the present times, as we are frequently called upon to cover large areas for occasional assemblies.

But as modern theatres were more to the point with students, the Professor called their attention to a magnificent work, lately published on "The great modern theatres of Europe," by M. Contant, which he exhibited.

The amphitheatre was then considered: although of early Tuscan origin, and originally formed in earth or scaffolding, it was not executed in permanent materials till the end of the first century. One in earth had been discovered by Sir C. Wren at Dorchester. That of Vespasian (as shown in a diagram) was too large for the site of Trafalgar Square, Charing Cross, &c. The velarium, 550 feet by 450, with which the colosseum was covered during exhibitions, was a surprising contrivance, and had been made the subject of a work by the architect Fontana. M. Hittorf had suspended the roof of a panorama in the Champs Elysées, somewhat in the manner of the Velarium, with great skill. This work, published, was here exhibited.

The gymnasium, in which the youth of Greece were instructed for the defence and honour of their country, in every department of prowess, was an interesting object of civil architecture. The plan of that of Ephesus, published by the Dilettante Society, was exhibited, and it was gratifying to observe the use which the late Professor Mr. Wilkins had made of this example, in illustration of the text of Vitruvius, which had hitherto been misunderstood.

The Gymnasium was the more interesting as the type of those Thermæ, the Roman baths, which have furnished the great school of architectural instruction, and from which the best inventions of the architects of the middle age, and of the revival, had been derived.

The name, Thermæ, as well as the express declaration of Vitruvius, declare that these institutions were exotic: a refinement adopted from Greece in the time of Augustus. During the first three centuries of our era, seven of these were erected; they were well calculated to indulge that love of luxury which rapidly corrupted the Roman manners under the emperors, as well as to gratify that constant excitement of novelty and splendour, which gave popularity to the government. Some idea of their extent may be conceived from the plan (exhibited) of the Baths of Caracalla laid down upon that plot which is comprised between Regent Street, Pall Mall, St. James's Street, and Piccadilly, covering about 28 acres. Cameron assures us, that those of Diocletian, somewhat larger, afforded hot baths for 18,000 persons at the same time: a bell rung at two o'clock to announce that the water was warm. The mask of a paternal urbanity was often affected by the despotic emperors, who frequently bathed with the people. One day Hadrian recognized an old companion in arms in poverty, scraping himself with a tile instead of the strigil; accosting him kindly, he furnished him with a slave, and all that could be wanted to his future comfort. Such an example could not but be infectious: accordingly when he came again, he was surrounded with poor acquaintances scraping themselves with tiles; but, calling them together, he observed, that being many they could scrape each other, without any superfluous expense of slaves or furniture. The Thermæ were in fact vast clubs, castles of indolence, in which every easy exercise of body or mind, and every delight of the senses might be indulged. The gardens, raised about thirty feet above the general level, were adorned with every fragrant shrub and flower; the choicest works of sculpture, obelisks and fountains, exedræ for the enjoyment of the shade or the sun (of a structure well worthy the student's attention) terminated the walks. In the central building was the great hall, the type of Gothic structure in ecclesiastical architecture, namely, the groined ceiling reposing on a column, and abutting on an extended pier, with the nascent flying buttress. The space of the naves (varying from 76 to 90 feet) being twice that of York, the widest of our cathedrals. The area covered, offers the largest space with the smallest obstruction in the support, of any scheme yet devised, and cannot be too much admired. It has been well observed of those structures, that we discern in them the type of all that has been since done in architecture, just as throughout the animal creation we trace the more or less resemblance to the type man. The interest excited amongst the French students recently (as exhibited in their late competition for the grand prize), promises that this admirable feature of ancient architecture will be reproduced in Europe before many years past. It was proposed for the new Public Library at Cambridge; it was employed by Sir C. Wren in Bow Church, on a small scale; and is executed on a still smaller scale, with considerable differences, but with happy application in the Bank of England, by Sir J. Soane. But the cloisters, the surrounding rooms and baths, their various forms and structures, and the happy union of the arch and the trabeated systems, would lead to more observation than can be here admitted. To the students he would say of them,

Nocturnâ versate manu, versate diurnâ.

Palladio designed to have published a book upon them, the drawings for which were afterwards edited by Lord Burlington. Mons. Blouet has published a magnificent work, giving all the restorations and details, which large excavations and very careful study of them enabled him to obtain.

The Basilica is also of Greek origin, as the name imports. The kingly hall was such as Solomon built in the palace of the forest of Lebanon. It was the Westminster Hall of ancient governments for administration of justice, commercial exchange, great public meetings, &c. The building at Pæstum, so called, was more properly a temple, because the Greeks were not accustomed to apply sacred architecture to civil purposes.

The Basilica of Trajan was the most magnificent exemplar of this species of building which the Professor could point out: with its forum, temples, and approaches, it covered 12 acres. The central hall or basilica, 540 by 168 feet, would contain St. Paul's in length and in width, exceeded only in the extreme ends of the cross. The central nave, 278 by 78, would contain the whole of Westminster Hall, in plan as well as in section. In Rome were 18 basilicas, and one at least in every city of the empire. Their subsequent adaptation to the Christian temple makes them highly interesting to the student. Vitruvius, lib. v. c. 1, describes the basilica, and his own work at Fanum, which differs from the usual form in some particulars.

Lecture IV.

Of the divisions of the art proposed, that of domestic and villa architecture alone remained to be considered. On this subject, two important preliminary remarks were to be made. Firstly, that the republican form of government, which prevailed in the ancient world after the seventh century B.C., greatly influenced the style of domestic buildings, which were expressly unostentatious externally, towards narrow streets, lined with shops, reserving all their elegance for the interior, in the atrium impluviatum—porticatum—the exedra, &c. Secondly, that populations and fashions having been derived from the east, an oriental character was impressed on the ancient habits and arrangements of countries in which (as in Italy especially) the northern and occidental now prevail; as derived from an opposite source. Whoever walks through the streets of Pompeia, after having resided amongst the Turks, will be struck with this fact. The profuse employment of water, in the bath, the impluvium, and in the corner of every street—the narrow street—the secluded mansions, within high walls—the internal air and space—the subdivision of the house into the men's apartments and the women's—the harem—the lightness of the costume—all express migration from warmer climates, and a marked distinction of the races of modern and ancient inhabitants.

The Jews lived chiefly on the terraced tops of the houses, as the Professor presumed the Pharaoh to have done. "Ahaziah" (II Kings, c. i.), King of Samaria, "fell down through a lattice in his upper chamber;" and it was thence that David, in a wanton moment, incurred the curse which fell upon his family. The house top is ever the scene of prayer. "Let him that is on the house top," says our Saviour, "not come down into his house, neither enter therein," (Mark, xiii. 15); yet it is possible that in the latter ages they had adopted the Greek and Roman ichnography—it was, perhaps, through the roof of the atrium testudinatum that the sick man was let down to be cured by our Saviour (Luke, v. 19.)

The narrowness of the streets, and unostentatious style of the houses in Athens, occasioned disappointment to the traveller, as Dicæarchus expressly tells us; in Rome the same; and as the houses were *limited* by the Augustan law to 70 feet high, we must suppose them unattractive. The fragments of the great plan of Rome, inscribed on the pavement of the temple of Romulus, by order of Septimius Severus, and published by Bellori, show the resemblance of the houses to those of Pompeia. It was an extraordinary innovation on the ancient humility of the Roman house, which Cæsar proposed, in demanding permission of the Senate to erect a fastigium, or pediment, over his door.

But the complete account of the Roman aristocratic house is to be found in the "Palais de Scaurus," by Mons. Mazois, as also of the citizen's house, in the "Ruines de Pompeia," so admirably illustrated by that ingenious and lamented architect.

But if the Roman nobles accomplished the admirable works described, in favour of the public, they did not neglect their own comforts. Under the empire they lived as individuals with the income of monarchs; and Strabo tells us expressly that "they built their villas after the palaces of the kings of Persia." The number of them was also extraordinary; for, as Lucullus said, "they were as wise as those birds which change their residence with the seasons."

Cicero had 19 villas, and it was in one of these that Cæsar honoured him with a morning call, and paid him the very high compliment of taking a vomit in order that he might do justice to his lunch. In another he delighted to ornament his library with Greek paintings and sculptures, which his friend Herodes Atticus was always collecting for him.

It was a fortunate legacy to the architect-antiquary which Pliny had left, in the description of his villa at Laurentinum. It had often employed the ingenuity of the architect, since the revival, but with small profit, till the discovery of the ancient ichnography of Pompeia. The Professor exhibited his own restoration, founded upon those data, in which, though he differed in some points from his accomplished friend, Mons. Haudebourt, in his elegant version of the Laurentinum, yet he strongly recommended it to the student, on account of the great research and taste shown in the composition. Some of the features he would describe. You entered a small tarium and thence a court in the form of the letter D, surrounded with a portico, which was enclosed partially with glass (the very original of our old conventual cloisters), and thus excluded rough weather. Thence through a gay court into a triclinium, which hung over the sea, and had windows all round three sides, giving the full enjoyment of the air, and view of wood and mountains beyond. To the left of this was a room, at the end of which was a rotunda (in apside curvatum), so contrived as to receive the sun's rays from the rising to the setting: in this was a case containing books, calculated to detain you, and such as "one loves to read over and over again." This arrangement afforded an angular parterre, protected on all sides except the south from the winds, and concentrating the sun's rays—a delightful refuge in the winter season. There were rooms heated by pipes from a hypocaustum, and others to retire to in stormy weather, to escape the roaring of the waves; a large bath for cold and hot bathing; a perfumery; and spheristerium, or fives court; a long gallery (crypto porticus) with windows on either side, which, when opened, admitted the fragrance of beds of violets, and the sun's rays at the rising and setting. "At the end of this," continues Pliny, "is a casino I built myself—my delight: in it I have an *Heliocaminus*, a sun chamber, warmed by windows all round; while reposing on my couch in a recess adjoining, I can see the garden, the landscape, and the sea, through a *glazed door;* I can study in perfect quiet here, and escape all the noise and disturbance of my servants, occasioned by the Saturnalia."

Pliny omits some features of great interest in the Roman house, as the Sacrarium, (the chapel,) in which the Lares (the household gods,) were placed, and sometimes the imagines majorum, of which the Romans, like ourselves, were justly proud. The Tablinium, for the archives, which also received these sometimes; and the Ergastulum, that room of the domestic side of the house in which chastisement was administered to the slaves, in the approved fashion of our schools at this day, as we see by various paintings preserved to us.

Pliny describes his gardens, his figs and mulberries, his gestatio bordered with box, and plantations disposed in the form of Xystus and the Hippodrome; classical titles, which give a charm to features otherwise insignificant: and since "the world," says Sir C. Wren, "is governed by wordes," they may often be adopted by the architect with good effect, when introduced appropriately and without pedantry.

The attention to the sun's rays in the milder climate of Italy, so conspicuously shown in Pliny's letters, is confirmed by all the authorities of antiquity.

Vitruvius (b. 6, c. vii.) is very particular in his recommendations to this effect; but the wisest of men, in a still warmer climate, has enforced this point yet more strikingly:—"To make a house pleasant," says Socrates, "it should be cool in summer and warm in winter: the building, therefore, which looks towards the south will best secure these objects, for the sun which will enter into the rooms in winter, will, by its greater altitude, pass over its roof in summer. For the same reason, these houses ought to be carried up to a considerable height, the better to admit the winter's sun; whilst those to the north should be left much lower, as less exposed to the bleak winds from that quarter: for, in short," continues he, "that house is to be regarded as beautiful where a man may pass every season of the year pleasantly, and lodge whatever belongs to him in security."

The modern Italians are not less attentive to aspect, which they significantly express by the proverb, "Dove non viene il sole, viene il medico."

But the most extraordinary villa of the ancient world, was that of Hadrian, at Tivoli, in which he displayed all the acquirements and collections of taste, during 21 years of constant travel through this vast empire; in it was reproduced every remarkable building of the world, and probably every statue of celebrity, since from this magazine the baths of Caracalla were furnished 80 years after, and the Vatican in some of its most precious ornaments. The whole was said to be inclosed in a wall 10 miles in circumference. Pizzo Legorio, Kircher, Contini, and Panini, have engraved and written upon the remains.

The modern villas of Rome, built by the popes and cardinals since the 15th century, convey to us some of those graces in which the ancient villas abounded. In these all the great masters of the revival have displayed their research and ingenuity. They are described in the elegant work of Messrs. Percier and Fontaine, to which the Villa Pia, by Mons. Boucher, has lately been added.

Our own architects of the 16th, encouraged by Bacon, Burleigh, and Wotton, certainly studied these works, and engrafted some of their principles on our Elizabethan architecture, which adapts itself admirably to our climate and the extent of our establishments. Bacon (Essays, vol. I.) describes his idea of a villa with great detail, insisting upon the aspect and the seasons as primary considerations. Indeed, all authorities agree upon this subject, except those of the 19th century, and especially the patentees of hot air or hot water apparatus.

"The Elements of Architecture," by Sir Henry Wotton, being "the Rules and Cautions of this Art cast into a Comportable Method," are amongst the most precious and the earliest in our language. He was long ambassador at Venice, from Elizabeth and James, and seems to have been personally acquainted woith Palladio. Domestic and villa architecture are special subjects with him; for, says he, "Every man's proper mansion and home being the theater of his hospitalitie, the seat of self-fruition, the comfortablest part of his own life, the noblest part of his son's inheritence, a kind of private princedome, nay, to the possessor himself an epitome of the whole worlde, may well deserve by these attributes according to the degree of the master, to be decently and delightfully adorned."

In truth, during three centuries the cultivation of this branch of architecture may be said to be peculiar to England, and that, while monumental and palatial edifices are better illustrated on the continent, the constitution of this country, and of the English mind—prone to the salutary retirements of home, the centre to which all its desires and warmest imaginings are ever pointing—have made the English house of every grade the most perfect in comfort and convenience, and the villa the beau idéal of individual possession, and the branch of the art in which our country excels beyond all others.

The compact square villa, after Palladio especially, was introduced by Inigo Jones, and much advanced by the model of those at Genoa, published by Rubens, who recommends them as full of beauty and convenience, and admirably suited to gentlemen of moderate fortune, such as the republic of Genoa is composed of. But the extension of the habits and the requirements of the present day have outgrown the spuare villa, and we are constrained to build a house beside the villa to accommodate them, with the worst possible effect in the group and in detail; for in vain the plantation attempts to hide it out; an anomalous composition is the result, and we had better have reverted to the Elizabethan mansion, which cast the house and offices into one in the extended E or H, or the French mansion, "enter cour et jardin," of the 18th century, reserving the centre for the best apartments, and the wings for offices, and the entrances in the angles communicating easily with all.

The least rational of English productions in this sort is seen in the castellated elevation adapted to this plan—the battlements and dungeon-keeps of Edward the Third upon the Italian villa of the 16th and 17th centuries. The menacing aspect, the machicolations, threatening hot lead upon the intruders, in the distance, are, on the approach, found to be peaceful and harmless; the fortress is accessible at every window, and expresses a security from danger on better acquaintance, in direct contradiction to its fortified exterior. On entering the baronial hall, where you expect the paraphenalia of chivalry and the chase, retainers and bondsmen, you are addressed by a powdered footman, or may discover a housemaid sweeping the marble pavement.

The Grecian villa is hardly better conceived; it may be taken for a library, or a philosophical institution. An extensive portico, borrowed from Minerva Polias, imposes its order on the whole composition, which is to be compressed accordingly, at the cost of all its internal proportions and accommodations. Every useful appendage of vulgar convenience is to be sxppressed, as ill-suited to its Flatonic refinement. As Swift says of Clelia—

You'd think that so divine a creature
Felt no necessities of nature.

But such architectural solecisms derogate from the dignity of the art, and convert into a theatrical or romantic dream, that which should embody sound sense and rational invention.

The essential features should be prominently expressed; the nobler portions, the offices, kitchen, the clock, and the stables, should tell their own story. And fiction would be found unnecessary when all these are placed in due subordination and proper character by the artist's hand.

France, until recent times, essentially monarchical and aristocratic, has ever delighted in palaces; and since the reign of Francis I., they have been the most remarkable of Europe. Du Cerceau, Philibert de l'Orme, Mansards, and Blondel, and many able successors, afford us the fullest information on the ichnography adapted to these grades. In conception and design, and in many respects in execution also, the Louvre is the most magnificent palace in the world, Situated in the metropolis, and occupying 32 acres, its galleries, and museums, and its gardens, form the recreation of the people. The paternal monarch invites them into his courts and vestibules, of which he esteems them the best ornaments, the most familiar and acceptable guests at all hours; participating with them his refinements and his delights, they are endeared and elevated, and the palace of the arts and sciences, a part of the entire composition, and ranging in the axis of the first court, forming the chief object from its windows, assure them of the nobleness of his views for their honour and real advantage. The palace itself, the work of centuries, still unfinished, is the great attelier of artists—the field in which they may exercise their genius for centuries to come in their several works—the great harbour in which talent may find protection and employment.

It was for the foundation of such schemes as these, that Francis I. invited Vignola and Serlio, and the painters of the school of Raphael, into France; and for their transmission to posterity, that he encouraged the publication of Cæsari Cæsariano's translation of Vitruvius, and the elementary works of Serlio and others, which obtained for him in return the title of the Father of Literature. Nor were his successors inferior in these encouragements, which enabled native artists afterwards to rival the great Italians—for L'Escot was preferred to Serlia, and Perrault to Bernini.

The peculiarity of French orthography is in the high roofs, subdivided into pavilians, affording great effect in composition of various and cumulating forms, aided by their high chimney shafts and dormer windows, and their vast windows below them, suited to the northern climate. Indeed, Philibert de l'Orme, and the architects of his day, have rendered the Italian style homogeneous with the northern climate and circumstances in the happiest manner.

A military people delight in pavilions; each apartment was to represent a tent. So in the Tuileries the line of tents is terminated with two, distinguished by the name of Pavilions de Flore and Marsan. A maritime people delight in their ships: thus the English apartments convey the idea of "between decks," and the larger buildings are often like the man-of-war hulk laid up in ordinary. So in Russia the palaces have the air of barracks; vast and forlorn, they remind the spectator of the plains of Siberia. In Egypt, the Troglodite excavation was revealed in the temple palace; in Greece, the log-house in the temple structure: in China, still the tent, in its simplest form.

In the middle ages domestic architecture arose from the monastic structures in single rooms, lighted on either side like our colleges, the chimney shafts issuing from the eaves. The composite house of double rooms was borrowed from the Italians by Francis I., but even there the *degagement* was wanting, and the chamber, ante-chamber, waiting-room, and guard-room, were all passage-rooms. It is in the English palaces that this problem has been best solved.

But the Professor observed, that this digression had led us from the chronology of the art, which terminated with the Roman villa; and we now entered that melancholy period of history, in which all ancient ideas of human enjoyment were absorbed in loftier and more serious aspirations; and the art during the next 1000 years was employed alone in military and ecclesiastical buildings, by means of the Freemasons. The original institution of that order is traced even to the Greeks and Romans. Numa established the first corporations of architects, Collegia Fabrorum, together with the inferior Collegia Artificum. They were invested with a religious character, and rights of framing laws and treaties amongst themselves. They greatly contributed to the increase of the Roman power amongst the barbarians, as have done our own people amongst the North American Indians, with whom an article of treaty on their part, has always been to send a blacksmith amongst them. The Collegia were greatly promoted by the Roman Emperors in the rebuilding of cities, in the aqueducts and public works, and endowed with peculiar privileges, as freedom from taxation, holding councils with closed doors, &c. Victor relates that Hadrian was the first to attach a corps of architects to the Cohorts about 120, A.D.)—an example which the admirable College for Civil Engineers at Putney, in favour of our colonies, promises to follow with great advantage.

But it was at the termination of the eighth century, that the masons of Como assumed their peculiar form of Freemasonry, raised into importance by the patronage of the commercial and zealous Lombards, in the building of churches and monasteries with new materials; and dispersed after the destruction of that kingdom by Charlemagne, they spread themselves over Europe, obtaining bulls from the Pope, and maintaining peculiar rights and mysteries. Collegia had existed in England; but, destroyed by the ravages of the barbarians, the Freemasons (probably of Como) were invited by Alfred, and after by King Athelstan, who gave them a charter in York (926), the original of which is said to exist still in that ancient city. It cites the Oriental Church, the history of architecture from Adam, with Rabbinical tales of the Building of Babel, the Temple of Solomon; Hieram, the Greeks and Romans, Pythagoras, Euclid, and Vitruvius, are quoted; that St. Albanus (300, A.D.) obtained a charter from King Carausius, with sixteen laws, agreeing with the *corpus juris*, relating to the Corpora or Collegia of ancient Rome. Another precious document preserved to us was written in 1450, under Henry VI., a great patron of architecture, published in the *Gentleman's Magazine* (1753, p. 417).

In 1459 a grand lodge was erected at Ratisbon, of which the architect of Strasbourg cathedral was the grand master. Charters and privileges were added by Maximilian, 1498. In 1717, Sir C. Wren was the grand master in England; but shortly after the ancient fraternity altered its original form and purpose, and became what we now understand by Freemasonry. Wren was then extremely old, and probably unequal to oppose the perversion which then took place; and which, from his known services to the craft, we cannot doubt was contrary to his wishes.

Thus the period of the revival was arrived at, and the Professor explained that in the previous and the present lecture he had devoted the more time to the review of ancient, sacred, and civil architecture, from the persuasion that the art would never again effect similar productions; therefore that antiquity formed that great storehouse from which the architect was to draw his best instructions.

It might be said, that the problem of architectural power and combination had been worked out and solved, that the mastery of the ancients was admitted, and that such works would never again be performed; it would not again become a primary instrument of civilization. The human mind had passed through that stage of its discipline, and had embraced new sciences, engaging the faculties in occupations more advantageous to the improvement and happiness of our species. The intellectual growth to the manhood of our nature, now perhaps attained, would esteem architecture ever a powerful engine in the attainment of the sublime and beautiful, but would probably never again indulge that preponderating regard given to it by the ancients.

The middle ages laboured after the ancient models with many divergencies: in the revival with the muses, the conviction of their pre-eminence was admitted, and their laws and principles were confessed as unalterable. Nothing then was wanted but to revive them, and the zeal with which this object was pursued was immense.

In 1416, Poggio Bracciolini, in searching for manuscripts, discovered a copy of Vitruvius, "covered with dust and rubbish, in a tower not fit to receive a malefactor," says he, "at the monastery of St. Gal, at Constance." Copies of this happy revelation were spread amongst the learned, until the invention of printing, in 1445, multiplied them amongst the great architects of the day—Brunelleschi, Cæsariano, Bramante, and others. The magnificent Alberti was one of the chief of these, but not finding in Vitruvius sufficient to inform and fire the student's mind, he composed that work which all competent judges have esteemed the most masterly compilation in the art extant. "Seeing," says he (lib. vi.) "that of all antiquity Vitruvius alone has reached us, that such chasms and imperfections appear in his work, that his help is insufficient: his language, too,—Greek to the Romans, and Latin to the Greeks—leaves so much unintelligible, I thought it the duty of an honest and a studious mind to free this science from ruin; though the rehearing without meanness, reducing to a just method, writing in an accurate style, and explaining perspicuously so many various matters—so unequal, so dispersed, and so remote from the common use and knowledge of mankind—certainly required a greater genius and learning than I can pretend to," &c.

But he did not confine himself to the theory of his art; as a scholar, a mathematician, a Platonist, and of a noble family, he associated with all the greatest spirits of his day, and was intimate with the living masters and the progress of their works. Whatever comes from him, therefore, is generous, moral, philosophical, practical, and elevating: he proves himself truly of the order of cavalieros; he mounts you upon his horse, which quickly you find a Pegasus: he raises you above the vulgar cares and labours of this nether world, and in his airy flight he shows you all the kingdoms of the world and their handiworks; and then he sets you down, cheered, instructed, delighted, and exulting in your profession.

The only English edition is that of Leoni, 1755. The spirit of that day deemed art a primary instrument of civilization; it became the boast and the occupation of the little courts of the rival states of Italy; literary societies, discussions, and conversaziones, discovered and refined upon the true principles of poetry and of fine arts; and a Bembo, Sadolet, Annibal Caro, Castiglione, Aretino, and a host of literary stars, all contributed their zeal and means to the æsthetical intelligence of artists. Architecture became the field of poetical imagination: and we have the 'Ὑπνοτερομαχια, "The sufferings of love in a dream," by the learned friar, Collonna, in which the wonders and delights of the art, and of its theories (full of original and beautiful conception, the source from whence the artists of the day drew continually), are accompanied with the romantic and amorous adventures of blighted love, of which the author was the victim. "The Dream of Poliphilus," printed by Aldus, in 1499, was published in French in 1600, with new plates, engraved from the drawings of Jean Gougeon.

From that period (early in the fifteenth century) to the present day we have a race of able architects in an uninterrupted chain, each adding some new grace or invention to the art, on which their merit and celebrity are founded; all these we now appropriate without appreciating their difficulties, and these progressions; or due acknowledgment to each for the contributions gradually made to our common stock. On the accompanying drawings of some of the great works of those masters, on which our present practice is based, the Professor proceeded to offer some comments. It must be premised that the revival found the art under very different circumstances. The growth of liberty in the middle ages, magnifying the individual, whose house now became his castle, an aristocracy balancing the kingly authority, the increase of commerce, and many other causes, altered the whole face of domestic architecture; it might safely be asserted, that no palace of the solidity of the Strozzi or of Burlington House, ever existed in antiquity. The remains of the most insignificant temples and public buildings are still found, but the absence of any remains of such solid mansions as those throughout the ancient world might be adduced in proof that the domestic architecture of the ancients was slight and ephemeral. The houses of the ancients, like those of the Turks, were of wood and brick, covered with plaster and with paint. Columns, indeed, abounded, but they were moveables, or furniture, the objects of manufacture at the quarries, and of trade. These reflections were sufficient to show, that the features which the architects of the revival, in their endeavour to restore classical architecture, introduced, were new in execution and design, and required a stretch and effort of mind which we do not sufficiently take into account. Those who may be considered the active restorers of architecture are—Brunelleschi, Bramante, Alberti, Peruzzi, Serlio, San Gallo, Michael Angelo, Raphael, San Micheli, Sansovino, Galleazzo Alessi, Vignola, Palladio, Scammozzi, L'Escot, Philibert de l'Orme; many others might be added, but none more remarkable than these. The question occurs, in what particulars were these men great? the answer will always be, that not only were they eminent practitioners, but they advanced their art, and contributed new views and inventions towards its perfection.

The first essays were in imitation of the system observed in the colosseum and the theatre, namely, the column and trabeation in relief, and superposed upon the frieze and arch, and this, in a small scale, formed a crowning order upon the tower on which Brunelleschi raised his dome at Florence. The same difficulties of constructing the trabeation, and of finding stone of sufficient size, and of funds for opening the quarries, which had induced the decline of architecture under Diocletian, occurred in its restoration; and it required the experience of one hundred and fifty years to suspend the disengaged entablature in the ancient manner, with any boldness of scale and projection, as in Perrault's Louvre, about 12 ft. 6 in.

Brunelleschi, in his church of St. Spirito and St. Lorenzo, employed the orders in good proportion, but these supported arches. The celebrity of Bramante's St. Pietro, in Montorio, doubtless arose, in great measure, from the accomplishment of the trabeated entablature, though the scale was indeed small, only 3 ft. 10 in. from column to column. But the timid application of the classical orders to the middle age buildings, often of large dimensions, gave them rather the character of trinkets hung upon them than of constituent parts of the fabric. Bramante, indeed, made a great step in the palace of Cardinal Wolsey, but the orders are still delicate in low relief, the windows circular-headed (from the difficulty of executing the square trabeated head) with the horizontal entablature above them. The basement, though elegant, has a gothic character, and the crowning cornice has but a small projection; the whole is dry and timid. But Bramante had the merit of inventing the coupled columns, which gave breadth and proportion to the front not otherways attainable. The ancients had left no examples of this disposition—but such were its advantages that it was at once accepted by Raphael and his successors; Perrault used it in the Louvre and Wren in St. Paul's.

Alberti's bold and master mind originated many of those features which his successors knew how to adopt, particularly in his church at Mantua; he gave the hint which M. Angelo followed in St. Peter's, of incorporating the whole height of the interior (not done till then) in one order, and vaulting the ceiling. His church at Rimini bears the stamp of Roman magnificence, quite beyond his age.

Peruzzi was the first to render his orders homogeneous with the structure, and his giving to the entablature of the upper order (especially in the Farnesina) a proportion suited to the entire height of the two, was as beautiful as it was new; it was afterwards adopted by Sansovino in the library at Venice with the greatest effect.

But Peruzzi executed an entablature in the Palace Massimi, and square-headed doors of no mean dimensions (six feet six inches between the capitals); but it was especially in perspective that he made advances far beyond the conception of his day. In other particulars, the merit of Peruzzi is unfolded by Serlio, his pupil, who possessed his collections and published them, through the patronage of Francis I., in the first elementary work on the art written since the revival. The first edition in French is dated Paris, 1545; it was translated into Italian at Venice, 1550, and, by Robert Peake, into English, 1611, under James I.

San Gallo was remarkable for the dignity which he gave to his buildings (especially the Palace Farnese), without the aid of the orders, except in subordinate dimensions, in the windows only, and in the interior court and vestibule. The verticality which is designed and usually conveyed by the orders he communicated to his buildings by rustic quoins, which carry the eye up, and enable it to embrace the whole front. This invention, which appears to be wholly his own, became popular and universal.

The windows, with their small orders, are undoubtedly taken from the Roman tabernaculum, or ornamented niche, so often seen in the baths and in the Pantheon, and was also a new application.

Raphael, as great in architecture as in painting, adopted his master Bramante's invention of coupled columns, as also San Gallo's windows and quoins, and if he did not invent, he employed the balustrade with singular grace and effect—for grace united with strength and nobility, his palace Pandolfini, Caffarelli, and Uggieri are unequalled; indeed, his letters show his enthusiasm for architecture, his profound estimation of the antique, and his ardent aspiration for the restoration of Rome to its antique character and splendour. The backgrounds of his pictures are not less to be regarded as examples than his executed works, being designed with as much care as if they were to have been perpetuated in marble.

M. Angelo distinguished his designs by vastness and singularity, compared with the previous schemes of Raphael, Peruzzi, and San Gallo. We are surprised at his boldness in proposing one order, eight feet in diameter, for the external front, and a corresponding disengaged entablature for an extended portico in the west front—which latter, however, was never attempted. His palace of the Capitol has many merits and peculiarities, one of which, practised in the Laurentian library also, was the sinking his columns in niches.

Vignola has been deservedly regarded as a master of the first merit, and has been hitherto the great authority in the French school, as Palladio has been of the English. His stereotomy, profile, proportion, and composition are admirable; his orders are generally subordinate, often at the top of his buildings—they are never coupled as in Bramante and Raphael, but he reconciles the wide intercolumniation by a panel which gives proportion and sustains the pilaster with excellent effect. This expedient, much followed in Italy and in France, was original with him, as was also his modillion cornice, extending to the frieze, and giving extent and importance to the entablature, proportioned to the whole height of the building, in a better mode than that of Peruzzi. This beautiful invention is recommended without ostentation:—"Questa cornice," says he, "la quale ho mesa piú volte in opera per finimento di facciate, ho conosciuto che riesce molto grata." This cornice was made the termination of the fabric, on which he never permitted a blocking or balustrade. But Vignola was chiefly remarkable for an artifice of composition, which, by subordinating the parts, gave apparent vastness to the whole; his doors and windows are remarkably small, the latter 3 feet 8 inches by 7 feet, only in Capralola—but, being finely proportioned and complete in their members, deceive the spectator into the belief of actual scale. This artifice has been much used by his successors, especially in the upper portions of churches, with good effect, where no means of comparison or admeasurement are offered, just as a man becomes a giant when seen upon a hill and against the clouds.

Sansovino, the Lombardi, and San Michele, Palladio and Scammozzi, formed a school peculiar to Venice, uniting sculpture in the happiest manner with architecture. In the library of Venice, one of the most beautiful buildings of the world, Sansovino adopted two orders, to the upper of which he applied the deep frieze and entablature suited to the *entire* height, after the invention of Peruzzi, the intercolumniations being occupied with the Venetian window, so much employed afterwards in England—these windows having columns doubled transversely in the thickness of the wall, by which an amazing solidity and richness is communicated to the architecture; an arrangement subsequently adopted by Palladio in his town house at Vicenza with admirable effect.

San Michele, chiefly a military architect, and who first gave the gates of cities the character afterwards universal, is remarkable for the energy, richness, and expression given to his works. His employment of the orders and of rustics is exemplary. His gates at Verona, and his palaces in Venice, especially of the Grimani, are masterpieces.

Palladio, by much the most laborious and learned architect of the revival, produced his effects by a happy employment of two orders, the one on a scale comprehending the entire height, the other subordinate, comprehending about two-thirds of that height. This principle had been employed by the ancients in the adjustment of side porticoes to the temple, and in the Propylea of Athens. In this last, the subordinate being 10, the principal is 15; in the Casa del Capitano, it is 10 to 16½; the same in the Basilica; in the Casa Valmarana 10 to 20½. This principle may be regarded as the secret of Palladio's magnificence, just as the subordination of windows and features was of Vignola's. But his employment of the arch in conjunction with the trabeated arrangement adopted from the baths, his classical plans, his mastery over all the features and parts of architecture, cannot be enough studied.

The two volumes on the architecture of Venice, by Cicognara—the single volume of the works of San Michele at Verona, by Albertolli—and the works of Palladio, by Bertotti Scammozzi, should be within the reach of reference to the architect at all times.

The pompous Scamozzi (braggadocio, as Inigo Jones calls him, probably from personal acquaintance, in his visit in 1614,) was a follower of Palladio, though he assumed to be an inventor. He was, however, the first to accomplish a portico, of any size, with a disengaged trabeation, in the church of the Theani. He was chiefly remarkable for the employment of orders above orders in well-studied proportions.

Galeazzo Alessi turned the peculiar locality of Genoa to immense advantage, and was the most active of those who have stamped upon the architecture of Genoa that sumptuous character so original and exemplary. This architect was in frequent competition with Palladio and Vignola at Brescia, Bologna, and other cities.

L'Escot and Philibert de l'Orme, in France, laboured with great advantage on the materials thus offered by the great masters of Italy; and they are chiefly remarkable for their adaptation of their inventions to the requirements of a northern climate, in large windows, chimney shafts, high roofs, &c.

The student will add many more peculiarities and titles of merit to the great masters of the revival from the hints here offered.

AN ARCHITECTURAL DOCTOR, AND ARCHITECTURAL IDLERS.

Sir—Whatever may be the merit of Mr. Gwilt's work, as one of elementary and practical instruction—and he must have been ingenious, indeed, to have got up so bulky a volume without at the same time bringing together information, new as such to many, if not to all—whatever merit, I repeat, it may so have, the intolerance and illiberality not only betrayed in it, but in many places openly expressed, are not very creditable to him, nor likely to recommend his book. The most that can be said in his favour is, that he does not stoop to flatter, nor has even attempted to conciliate the good opinion of, those whose opinion is likely to have some influence in stamping the character of his "Encyclopædia." It is to be hoped that the bulk of the profession—at any rate those who follow it as a liberal art, do not at all agree with him in his "bow-wow" depreciation of a class of persons to whose labours in the study of Gothic architecture we are greatly indebted, and professional men themselves not least of all. It may be fairly questioned if that style of the art would have been revived among us at all, but for the diligence of extra-professional students, and the attention directed to it by their writings.

It might be thought that, if not disinterested generosity, at least a sort of enlightened and generous selfishness would induce architects to encourage as much as possible a taste for the study of their art—and without some study, a taste for the art itself cannot be acquired—and to aid in removing the prejudices which deter persons in general from approaching it, under the false notion of its being entirely a practical one, mechanical, dry, and repulsive. Whether any of his brother architects will now side with Mr. Gwilt, remains to be seen; but in my own opinion they have very little cause to congratulate themselves upon having a champion in their ranks, who would show his prowess by hewing down, and putting *hors de combat*, all the volunteers engaged in the same cause. Much liberality I did not expect from Mr. Gwilt, but I certainly did suppose that he would exercise a little more discretion than he has done. I did not, for instance, imagine that he would allow his antipathy to German architecture to prevail so far, as to give no account of any of the numerous fine buildings erected in that country during the last 30 years; and as not to applaud the zeal with which architecture is there cultivated, if he could not say much in favour of the taste displayed in it. Had he done so—and the same with regard to other countries, those chapters of his work might have been made to contain a great deal of quite fresh and valuable information. The reason assigned by him for not doing so, is a most flimsy and childish one—perfectly ridiculous; for according to that, there ought to be no such thing as criticism on contemporary works at all; nor ought any to have yet appeared relative to those of a Thorwaldsen, a Cornelius, and other great living masters in their respective arts. Besides, he might have executed that part of his task very *innocently*, and without giving the slightest umbrage to any one, by abstaining altogether from criticism and comment, and confining himself to description and mere matter-of-fact information. At present, his apology for passing over altogether what he was conscious would naturally be looked for, sounds too much like the fox's—"the grapes are sour." The real reason, there can be very little doubt, was his inability to make the necessary research, and collect materials for that part of his work, wherefore he would have done well to obtain assistance for it. Considering his avowed and unqualified dislike, or I might say, hatred of modern German architecture, it is not very surprising that he should not have referred us to any of its chief productions, lest the bare mention of them should be mistaken for approbation. Yet neither does modern Italian receive better treatment from him, for he says nothing of what has been done in that country, within the present or even the last century, excepting the palace at Caserta. There is not a syllable relative to such architects as Calderari, Temanza, Selva, Piermarini, Cagnola, Niccolini, and a great many others, whose works display quite as much ability and taste as some of those which he most highly praises. Nay, though he expresses so very high an opinion of modern French architecture generally, it is only in general terms, without either describing any thing of the kind, or showing it in a wood-cut. In fact, he has not introduced any fresh subjects among his "illustrations;" and of his "more than 1000 engravings on wood," the greater part are mere diagrams, and the rest of very ordinary character. What will ultimately be *that* of his "Encyclopædia" itself, may easily be guessed, for most assuredly it will not obtain a very flattering one either from students of Gothic, or admirers of German architecture, both of whom will not only be disappointed in it, but offended also, more particularly the former, since they are by no means likely to relish the insolently sneering and contemptuous tone in which Mr. G. speaks of the "literary idlers, especially at the universities," who amuse themselves with inquiring into the history of Gothic architecture; which censure, we must suppose, extended by him also to such publications as those by Parker, and Bloxam, their object being to aid, encourage, and promote the study of it, not at the universities alone, but all over the kingdom. But the popular current against which Mr. Gwilt swims, may overwhelm both him and his book; therefore, his opinions may do no great harm after all. What is chiefly to be regretted is, that his "Encyclopædia" is likely to stand for some time in the way of any better publication of a similar nature, because, though there is ample room for one, in one sense, the market for it is, or will be thought to be, pre-occupied.

I remain,

Yours, &c.,

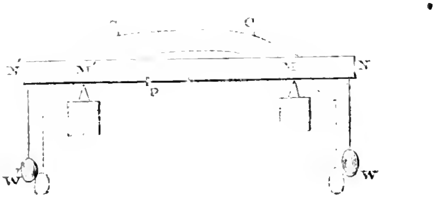
"A Literary Idler."

ON THE STRENGTH OF BEAMS.

Sir,—One of the greatest advantages which the practical man has over the theoretical, is that of being able to discover any *great* error in a design by mere inspection; this facility in discovering serious mistakes at a "*coup d'œil*," is only acquired by men of great practical skill and long experience, and is a faculty too frequently dearly bought by many failures: the practical man, in forming a design for a bridge or any mechanical structure, seldom uses anything besides a scale and pencil; he rarely commits any great error, but also he is rarely exactly right; on the contrary, certain data being given to the theoretical man, he enters into calculations mostly always long and intricate, and forms his design according to the dimensions obtained from his results: he frequently commits a mistake in his calculations, omits the consideration of some modifying circumstances, and thus his design is faulty, and frequently is only discovered to be bad when the structure falls to pieces; even then he will certainly lay the blame on the builder, like a celebrated French engineer who, being told that a large bridge built according to his design had given way on the striking of the centering, would not believe it, saying, "Impossible, I calculated its dimensions to the greatest nicety."

The sensible engineer will combine theory and practice, and giving to neither undue preponderance, will certainly, *ceteris paribus*, produce the most perfect design; he will neither trust too much to the eye nor rely implicitly on his calculations, and thus he will avoid such a serious error as that which I committed, in my answer to the question on the strength of beams, proposed for solution by "Concrete," and which appeared in your *Journal* of last month; if I had constructed the result obtained by algebra and made a sketch of the beam corresponding to that answer, in short, if I had followed the advice given above of not trusting too much to your calculations, but correcting them by the eye, I should at once have perceived my gross mistake, viz., that of multiplying, instead of dividing, the momenta of the weights by the internal leverage of any point, in order to find the counterbalancing weight.

By correcting the error myself, I shall prevent much useless discussion and comment from your Argus-eyed readers; at the same time I shall briefly explain what I conceive to be the real solution of the question. I stated in my letter of last month, that the true and best form to give to the beam is the parabolic: this being however deduced from erroneous calculations, must be altered, and a result much more simple and satisfactory will ensue by modifying the equations in one or two steps, dividing, in place of multiplying, the momenta of the weights by the lengths of the internal segments at any point between the supports, in order to find the equivalent weight there. For the purpose of rendering my explanation more clear, and making the action of the weights on a beam so circumstanced, more intelligible, I add a sketch of the form it will assume before it attains the point



of fracture. N', M', M, N, is the beam resting on the supports M', M; the distance between these is 6 times that of the points of support (M', M,) from the extremities N', N, to which the equal weights W', W, are applied, to find the best form of the beam between the points of support. On first applying the weights, the part between the supports cambers, as represented in the sketch by the dotted line, and assumes a circular form, becoming more flattened at the centre as it approaches the point of fracture, and ultimately breaks at or about the points c, c,. I am indebted to a friend, on whose accuracy I can depend, for the account of the experiments from which this explantion has been deduced; you will observe how precisely it agrees with Concrete's statement of the points of fracture as deduced from his own experiments; I must here apologise to him for having cast a doubt on their accuracy; I could not account how the beams could give way at these points; which more particularly made me suspect some error, is his statement that the bar of iron broke in *two* points. The experiments I brought forward in support of my explanation in your *Journal* of last month, were conducted on such a small scale that I am not in the least astonished at the fact of the model yielding in the centre. It appears from the above sketch how the beam may remain in a very curved position without breaking; the leverage of the weights decreasing as the beam approaches the point of fracture. In the following investigation, I shall however omit the deflection of the beam and its weight. What then is the weight which, placed at any point (P) between the supports, will balance the two external weights, and what is the effect of its strain at that point?

From the principle of the lever, it is found equal to W. MN ×

$\frac{MP + MP}{MP \times MP}$; but the strain of any weight at the point P, as is proved in all works on mechanics, is expressed by the product of this weight, and the fraction $\frac{MP \times M'P}{MP + M'P}$, and consequently in this case by W × MN; that is the momentum of the external weight, a constant quantity, but since the strength of the beam at any point is proportional to the breadth multiplied by the square of the depth, the breadth being the same, it ensues that the beam should be rectangular. If the weight of the beam was taken into consideration, it would appear that the depth of the beam should slightly increase from the centre to the supports; and it is because this weight acts with greater effect at the centre that, in the experiments alluded to above, the beam broke near the supports. In practice, therefore, the beam should be made *rectangular*, unless its weight be considerable, in which case its depth should slightly increase from the centre to the supports, according to a law easily deduced by introducing the action of its weight at any point in the above equations.

The strain at any point between the supports is W. MN, and at any oint outside the supports, W multiplied by the distance of the point pom the extremity. The strain is therefore less externally than fr ternally.

You would greatly oblige me by inserting this letter in your next number.

I remain, Sir,
Your obedient,
T. F——x.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

INSTITUTION OF CIVIL ENGINEERS.

Annual Meeting, Jan. 17, 1843.

ANNUAL REPORT.

This report contains a reference to the proceedings and principal papers read before the Institution last session, and which have been reported in the *Journal* of last year; likewise the receipts and expenditure of the past year, and the following obituary:—

We have to regret the decease of the Right Honourable Lord Congleton, Mr. Samuel Seaward, Mr. Benjamin Hick, Mr. Charles Collinge, Mr. W. D. Anderson, Mr. John Smeaton, and Captain Foster, Bombay Engineers.

LORD CONGLETON.—Sir Henry Parnell was born in the year 1776. After the usual routine of university education he entered early upon a parliamentary career as member for Queen's County, and became distinguished for his steady industry and application to business; his speeches abounded with facts and calculations, and in many political as well as financial questions he took a prominent part. In 1828 he was appointed chairman of the Finance Committee; subsequently he became Secretary-at-War and a member of the Privy Council; in 1835 he succeeded Lord Lowther in the office of Treasurer of the Navy, with which were consolidated the duties of Paymaster-General of the Forces and Treasurer of the Ordnance, which combined office he held until his elevation to the peerage in 1841 as Lord Congleton of Congleton, in Cheshire. These public duties did not prevent him from filling numerous private offices, among which must be principally noticed that of chairman of the Commissioners of the Holyhead Road. This post naturally created an intimacy between him and our first president (Mr. Telford), which was only interrupted by the death of the latter. The active mind of Lord Congleton being thus directed to engineering pursuits, he cultivated the society of other civil engineers, and became an honorary member of this Institution in 1833; his Treatise on the Construction of Roads, and his plan (adopted by the Post-office) for improving the construction of mail coaches, show that his acquirements in the practical details of professional subjects were not superficial. He published also several works on finance, banking, and the currency, besides pamphlets on Catholic Emancipation and other political subjects. The decease of his Lordship took place in the sixty-sixth year of his age, respected as a public character for his attainments, his general consistency, and his great industry, and regretted by a large circle of private friends.

MR. SAMUEL SEAWARD, F. R. S., &c., was born at Lambeth in the year 1800, and at the age of fourteen years he entered the service of the East India Company as a midshipman: after his second voyage to Bombay and China he relinquished a naval career, and was placed by his brother as an apprentice with the late Mr. Henry Maudslay, in whose establishment he had the best opportunities of acquiring a practical knowledge of mechanics and engineering; of these opportunities he carefully availed himself, and always cherished a grateful recollection of his instructor. After passing about five years with Mr. Maudslay, he entered the service of Messrs. Taylor and Martineau, whence he proceeded to Cornwall, and assisted, under the direction of Mr. Arthur Woolf, in the erection of several large pumping engines; he then undertook the superintendence of part of the works of Mr. Harvey, at the Hayle Foundry, where he had the advantage of the instructions of Mr. Richard Trevithick. In the year 1825 he returned from Cornwall and joined his brother, Mr. John Seaward, in the Canal Iron-works, Limehouse, as manufacturers of marine and other steam engines, as well as of general machinery. The attention devoted by Mr. Seaward to the construction of marine engines particularly, and the successful adaptation of the "direct action" engines[1] (which were, it is believed, first introduced by Mr. Gutzmer, of Leith, on board the *Tourist* steamer), are well known in the profession. His ingenuity and mechanical talents are manifested in all the works undertaken by the firm to which he belonged, and by several scientific pamphlets which he published. He joined the Institution in the year 1828, and became subsequently an active and useful member of council, and our Transactions are indebted to him for a memoir "On the application of Auxiliary Steam Power to sailing vessels on long Voyages." Snatched from among us at the early age of forty-two years, the profession has lost an intelligent and zealous member, and his private friends a worthy and estimable man.

MR. BENJAMIN HICK was born at Leeds in the year 1790, and was brought up as a practical engineer in the establishment of Messrs. Fenton and Murray, by whom at an early age he was intrusted with the superintendence and erection of several large engines, &c., and he was eventually offered a partnership in their works; this he declined, and in 1810 engaged with Mr. Rothwell in the Union Foundry at Bolton, of which he was the managing partner; and in 1833 he established the Soho Foundry, now carried on by his sons in that town. His attention was directed to almost all branches of mechanics, and the ingenuity displayed in his inventions and improvements is generally acknowledged: some of his improvements have become public property without being claimed by him, or its being known from what source they emanated. He became a member of the Institution in the year 1824, and although the distance of his residence precluded his frequent attendance at the meetings, he was a liberal contributor to the collection of models, &c. His good taste, his integrity of character, the encouragement which he extended to talent of all kinds, and the assistance given by him to all public improvements, obtained for him considerable influence in the town of Bolton, where his loss will be much felt.

MR CHARLES COLLINGE was born in the year 1792, and being engaged from an early age in mechanical pursuits, he eagerly embraced the proposition of your vice-president, Mr. Henry Robinson Palmer, to unite with him and a few more young men[2] in forming a society for mutual improvement, by discussing scientific subjects; from this commencement, in the year 1818, has arisen the Institution of Civil Engineers, which now numbers five hundred and twenty-five members of all classes. Mr. Collinge continued, through all the stages of its progress, an useful and active member; he took his share of the duties as a member of council, and filled the other offices of the Institution with readiness, and his attendance at the meetings was very constant.

MR. W. D. ANDERSON was a pupil of our first president, Mr. Telford, after whose decease he travelled in Italy, whence he sent to the Institution a series of drawings of the Ponte Santa Trinita at Florence. On his return he was engaged under Mr. W. Anderson (his father), the engineer of the Grand Junction Water-works, on several surveys and other works. He then gave plans for, and was appointed engineer to, the Exeter Water-works, which situation he resigned in 1837, in order to become engineer to the corporation of Newcastle-on-Tyne, where he constructed some important works. Ill health obliged him to resign this latter appointment in the year 1841, and his decease took place during the last summer.

MR. JOHN SMEATON and Captain R. FOSTER, Bombay Engineers, had only been elected during the past session, and owing to the sudden decease of the former, and the shattered health of the latter, consequent on a lengthened residence in the East Indies, they had scarcely ever been able to attend the meetings of the Institution.

ADDRESS OF THE PRESIDENT.

Before I resign this chair I have to perform the pleasing duty of thanking you for your attention to the Institution, which has enabled your Council to present to you the satisfactory Report that has just been read, and has rendered the discharge of my duty so agreeable. I take advantage of the opportunity thus afforded me, to refer to some points which may not be considered strictly within the scope of the Report of the Council.

Honorary Members.—The Report has informed you of a considerable addition to the list of Honorary Members, by the election of several distinguished individuals.—The following is a list of the Honorary Members referred to:—Field Marshal the Duke of Wellington; the Duke of Buccleuch and Queensberry; the Marquis of Northampton, President of the Royal Society: the Lord Chancellor Lyndhurst; Lord Brougham and Vaux; Sir Robert Peel, Bart., First Lord of the Treasury; Charles Shaw Lefevre, Speaker of the House of Commons; Professor Airy; the Rev. Dr. Buckland; and the Rev. Dr. Robinson, of Armagh. These have been elected, not on account of their rank alone, but because with rank, they hold, or have held, high stations, or have been placed in situations in which they have shown

[1] The engines of the *Gorgon*, the first of a numerous class of Government steamers fitted with that kind of engine, were built at the Canal Iron-works.

[2] Messrs. H. R. Palmer, J. Field, W. Maudslay, J. Jones, C. Collinge, and J. Ashwell.

their desire to advance the sciences or arts connected with Civil Engineering; or because they are themselves eminent as men of science and learning. None of them were proposed until they had, like all other candidates for election, expressed their desire to become Members; and in many instances their wishes have been communicated in a manner highly complimentary to the Institution and to its objects. Indeed it is impossible that public men, who have held the highest offices, possessing only the tithe of the understanding of a Wellington, a Brougham, a Lyndhurst, or a Peel, can be indifferent to the growing importance of engineering to the welfare of this country, or not aware that the greatness, I may, perhaps, be justified in saying, and even the existence of the nation, mainly depend on it. It has been said that the steam engine, rendered powerful and practicable by Watt, fought the battles and gained the victories of the last great war; that by it the mines were drained, and the ores and coal raised, which, when applied to Arkwright's and other improvements, multiplied in effect the power of the country, reducing the price of mechanical labour a hundred-fold, and enabling us to supply foreigners with our manufactures, for which they returned us the sinews of war; and that, hence, notwithstanding an expense, beyond all precedent, continued for a quarter of a century, the country, even if the increase to the national debt were deducted, was richer as well as more powerful and more populous at the end than at the beginning of the war. In this there is much truth, but the effect being indirect is not so obvious. In the late Syrian and Chinese wars, however, there could be no doubt. In both cases the work was done chiefly by steam ships of war; and it could not have been done so quickly or so effectually in any other known way. The steam engine, therefore, may now be considered the great power in war as well as in peace; and hence, in another light, the immense importance of the objects of this Institution, when it appears that the long-boasted wooden walls of Old England will henceforth be comparatively inefficient without the co-operation of steam. I do not mean by this to express any opinion of the justice or policy of the late wars—the most glorious part of them was, in my opinion, their termination. My object is to show why the lately elected honorary members have naturally been desirous of becoming so; why we have elected them, and why we may expect them to take an interest in our proceedings and our progress. But there are other considerations more congenial to our civil position in which the individuals who have not written and published scientific works are to be regarded as worthy of the membership.

Sir Robert Peel, now at the head of the government of this country, has not been unmindful that to the application, by his enterprising parent, of the discoveries of Watt and Arkwright he owes the position and education which started him in public life. At the public meeting in 1824, for erecting a monument to Watt, Sir Robert, then Mr. Secretary Peel, said, "that he belonged to that very numerous class of persons who had derived a direct personal benefit from the important discoveries of Watt, and he acknowledged with satisfaction and pride that he was one of those who derived all that they possess from the honest industry of others." His connexion with us is therefore natural: and by evincing his desire to promote science and the useful as well as the fine arts, he has proved, and I am sure will continue to prove, himself a useful as well as an ornamental member.

The Duke of Wellington, in being, while in office, mainly instrumental in recommending the means for proceeding with the Thames Tunnel, and for completing the approaches to London Bridge (one of the greatest metropolitan improvements), considered that he only did his duty; but Sir Mark Isambard Brunel, and Mr. Jones (Chairman of the London Bridge Committee), consider that to his Grace is mainly due the merit of these great works; and that as Lord Warden of the Cinque Ports, he has always taken a lively interest in the works of Dover Harbour and other improvements upon the coast, I can bear witness, as well as to his knowledge of works of civil engineering, which he has lost no opportunity of cultivating. His Grace's reply to a question by me, as to how he came to know so much of the different plans of sluices for draining, &c., was, that when with the army in Holland and Belgium he had plenty of time to ride round the country and to examine them.

The Duke of Buccleuch has, in being the liberal President of the College of Civil Engineers, shown his desire to advance the profession; and in the formation of mines, railways, roads, bridges, and piers, upon his extensive estates, he gives the best practical illustration of his taste for works of engineering, and his wish to promote the objects of this Institution.

Earl De Grey, as President of the Institute of British Architects, himself in taste an architect, and aware of the close connexion between architecture and engineering, has abundantly shown the interest he feels for our success and progress.

The Marquis of Northampton, as President of the Royal Society, would have had sufficient passport for membership, even if his zeal for science, particularly geology, which we all agree with Dr. Buckland to be intimately connected with our profession, were not known. At the last anniversary of the Royal Society, his Lordship, in proposing as a toast the success of this Institution, referred in very flattering terms to its importance and future prospects.

The Speaker of the House of Commons, Mr. Shaw Lefevre, has been a fellow-labourer with our associate, Mr. Handley, in the application of engineering to agriculture,—not only in the drainage of great districts, but in machinery of all kinds, from the steam plough downwards.—Our member, Mr. Parkes, could fill up a long list of Mr. Shaw Lefevre's exertions in this way. As a Commissioner, *ex officio*, of many of the most important public works, I have witnessed his attention to details which, unless he were fond of engineering, he would not think of, even if he had more leisure than the onerous duties of Speaker of the House of Commons allow him.

I might proceed to remark on the other recently elected honorary members, but they are so well known, and have by their writings shown themselves so qualified, that to do so would be an unnecessary occupation of your time.

The late Mr. Ewart.—Having referred to the subject of our steam fleet, I may mention that, until the year 1835, there was no chief engineer and inspector of machinery for the navy, and that Mr. Peter Ewart, who died during the last summer, first held that office. As he was not a member of the Institution he is not noticed in the report of the Council; but the situation he held, and his talents, will, I trust, be considered sufficient to make acceptable a short notice of some facts respecting him.

Mr. Ewart was born on the 14th of May 1767, at Troquaire Manse, in the county of Dumfries. His father, and two or three generations before him, were clergymen of the church of Scotland. Peter was the youngest of a family of ten children (six sons and four daughters). The father's care was divided between the duties of his parish, his private studies, and the early education of his family, which he superintended,—the result proves how successfully; two of his sons having been well known as among the most eminent merchants in Liverpool, and a third as Envoy of this country at the Court of Berlin, where he died at the early age of 32 years. At nine years of age Peter was sent to the Dumfries parish day-school, where he had the benefit of good masters, particularly of Dr. Dinwiddie, an excellent mathematical teacher. At this period his natural turn for mechanics showed itself. His hours of recreation were spent in the shop of a watch and clock maker (named Crocket), which lay between the school and his home; and so well did he profit by what he saw there, that at the age of twelve he had, from materials which he had collected, made and finished a clock that performed well, and was the most interesting piece of furniture in his bed-room. In his fifteenth year he went to Edinburgh and attended a course of lectures, probably those of Professors Robinson and Playfair, as these distinguished philosophers were subsequently on the most intimate terms with Ewart. John Rennie, the late eminent engineer, had a short time before this begun business as a millwright in East Lothian, and on Ewart's leaving Edinburgh he was sent to Rennie. Ewart told me that he was Rennie's first apprentice; that Rennie had one journeyman; and that one of the jobs of the trio was the construction of a small water-mill (the Knows Mill), upon Phantassie farm, for which a shed was lent by Rennie's elder brother George, who afterwards stood as high as an agriculturist as his brother John did as an engineer. He described to me the scene that took place on the day this mill was started, when, inspired by the success of his first work, his master foretold, to the astonishment of his journeyman and apprentice, his own future greatness.

The facts that the celebrated James Watt was about this time employed in the erection of his steam-engine to work the Albion Mills, which stood at the south-east angle of Blackfriars Bridge, now Albion-place, that he applied to Professor Robinson to recommend to him an intelligent well-educated mechanic to superintend the mill-work, and that Robinson fortunately recommended Rennie, the Lothian millwright, who had distinguished himself in his class, are well known. And here I would call the attention of my young friends to the illustration which Robinson's recommendation, as well as Rennie's success, affords, that a practical knowledge of millwrighting is one of the best, if not the very best, foundation for engineering. Soon after Rennie's arrival in London he sent for his apprentice Ewart to assist him in the erection of the mills,—a proof of his opinion and his friendship. Ewart followed his master. How well he had calculated the expense of the journey may be collected from the fact that the last penny he had was paid as toll for passing Blackfriars Bridge to enable him to reach the mill. For four years, 1784 to 1788, Ewart worked as a millwright at these mills, whence he was sent by Mr. Rennie to Soho, to construct a water-wheel for Mr. Boulton's rolling-mill, and was afterwards taken into the service of Boulton and Watt, to erect their steam-engines. There he had ample scope for his abilities, and the advantage of Watt as his friend; this friendship terminated only with Watt's life, and was continued by the present Mr. Watt, whom I have often heard speak with the greatest respect of Ewart's abilities and excellent qualities.

In 1791 he was sent by Boulton and Watt to fix one of their engines upon the cloth-works of Benjamin Gott and Co., Leeds. Mr. Gott, who was then a young man, and became afterwards one of the most public-spirited and liberal, as well as greatest manufacturers in this country, was just the person to appreciate Ewart's qualities; the engine superintendent became his friend, and that friendship remained firm and unchanged for nearly half a century. I have heard Mr. Gott speak in the highest terms of Ewart. The following anecdote, told me by Mr. Gott, proves that others well able to judge entertained the same opinion. A gentleman speaking of Ewart at Gott's table, said he had met with but few better practical mechanics than Ewart. "You have been a fortunate man," said Professor Playfair, who was of the party, "for I have never met with one." In 1795 and 1796 he assisted the present Mr. Watt in planning the buildings and works of the Soho foundry, shortly after which, he quitted engineering as a profession, and became a manufacturer, first at Stockport with Mr. Oldknow, then shortly after in Manchester with Mr. Gregg, and afterwards he took a cotton mill on his own account. His bias being always so much towards mechanics, it is not improbable that his idea was that he could make great improvements in the cotton machinery, and that this led him to engage in the business of a manufacturer.

Ewart remained in Manchester in constant association with Dr. Dalton, Dr. Henry, Mr. Kennedy, and other eminent men, until 1835, when he was recommended by the present Mr. Watt to the Admiralty as a proper person to fill the situation which he held until the time of his decease, on the 15th September, 1842, then in his 76th year. His health had been delicate for some time; but the immediate cause of his death was a blow from the end of a chain which broke when he was standing near it in the Dock Yard at Woolwich. Notwithstanding the long interval between his quitting the practice of engineering and his returning to it, and notwithstanding his age (68 years) when he undertook the office, he gave, so far as I have ever heard at the Admiralty or elsewhere, great satisfaction. The professional responsibility, in his own department, of the steam machinery of the British navy rested upon him, and how well he acquitted himself is proved by the results in China and Syria, and in almost every other quarter of the globe.

Mr. Ewart's change of employment for so long a period of his life has caused his name and character to be less generally known than they deserved to be. Like Playfair, I may say that I never met with a man who had so general an acquaintance with engineers and mechanical men of his own time as Ewart had, but he was not easily brought out. I have often pressed him to record in some way his great store of anecdotes and interesting facts, but my doing so was in vain. To write or even to speak on matters in which he had taken an active part appeared painful to him, and was never done when with more than one or two friends. His knowledge of machines, and particularly of the principles of the steam engine, was very intimate. His admiration of Watt, and his practice at Soho, inclined him to view with some degree of scepticism any innovation in the engine, which he considered to have been almost perfected by his great master; and, for the public situation which he held, this prejudice was probably useful, for the war steamers in active service are not those in which new schemes should first be tried.

Ewart was a warm and persevering friend to merit. My friend, Mr. Hartley, engineer to the Liverpool Docks, considers that he owes his appointment chiefly to Ewart's exertions in his behalf, and Ewart was ever afterwards ready to assist Mr. Hartley with his scientific opinion. Mr. Hartley is conscious of the advantage he derived from it, and considers that by Ewart's death he has lost his best and ablest friend and counsellor. Sir Edward Parry (the comptroller of steam machinery to the navy,) in a note I have lately received from him, states, that "after more than five years' constant and intimate acquaintance with Mr. Ewart, he must declare that he never met with a man of sounder judgment, more amiable feelings, or stricter integrity of purpose; and that he felt he had, at his decease, lost an esteemed friend, as well as a valuable coadjutor in the public service." Sir Edward's note then refers to the late results of the war in Syria, and still later in China, in which he says, "the mighty power of steam played so decisive a part, that these wars, humanly speaking, may be said to have been entirely terminated by steam."

I will close this subject with an extract of a letter, dated in 1793, from Dr. Currie of Liverpool (the elegant biographer and editor of Burns), to Mr. Wilberforce. The letter is given in the first volume of Wilberforce's correspondence. It appears by the description that at that time the distress of the cotton manufacturers was greater than even anything of recent date; that the workmen were in a starving state; and that Ewart, the partner of Oldknow, went to Liverpool to represent the extreme case, and endeavour to obtain the attention of ministers through the members. He had a meeting with Dr. Currie, who writes thus to Wilberforce in order to increase his attention to the statement of the case.

"(Ewart) is no common character; he was with Boulton and Watt as superintendent of machinery, and has an extraordinary degree of the most useful knowledge of every kind, and in a word is one of the first young men I ever knew. These qualities recommended him to the notice of the manufacturers, among whom he exercised his profession of mechanic and engineer. He had offers of partnership from the first houses there, and was actually taken into the house of Mr. Oldknow (of Stockport), at that time the first establishment in Lancashire. Mr. Oldknow was the original fabricator of muslin in this country, and a man of first-rate character."

Mr. Cotton.—Having referred to the countenance received from distinguished noblemen, I must not omit also to say how proud I am of the communications and presents we have received from my excellent friend Mr. Cotton. Ewart was not more devoted to Watt than Cotton was to his late friend Huddart, whose portrait is, through Mr. Turner's kindness, before me. Watt and Huddart were indeed kindred spirits, I have often seen them together, and at the time and since I have often thought that never were two men better paired in person and bearing as well as in mind. Mr. Cotton was the friend of both. Being governor of the Bank of England, and therefore filling the highest office in the greatest corporation in the world, he has given us very decided marks of the estimation in which he holds us. Following his friend Huddart in the march of mechanical improvements, Mr. Cotton has invented a very beautiful machine for weighing gold coin: it is now used at the Bank, and from his uniform attention we may expect soon to have it brought under our notice.

Thames Tunnel.—Among many engineering works of which this country is possessed, none has, during its execution, attracted so much public notice as the Thames Tunnel, and this even more in foreign countries than in England. In October 1842 the shield reached the shaft on the Middlesex side; and we may therefore congratulate Sir Mark Isambard Brunel in having, so far as the great engineering work goes, completed the tunnel, and accomplished the great wish of his heart. With the amazement with which foreigners consider the abstract notion of a tunnel under the Thames, we in this country of mines and tunnels do not sympathize. We know that if the tunnel had been through the London clay or the chalk, there would have been little difficulty; but this was not the case; the strata were of the worst kind, often entirely silt and quick-sand, which were forced through the smallest apertures. At these times the iron of the shield, little more than an inch in thickness, was the only division between the tunnel and the Thames. On three occasions this ever-watchful enemy succeeded. The second irruption, which took place on the 14th January, 1828, was the most serious, as then not only was the whole tunnel in possession of the Thames, but the shield, the invention of Brunel, and by which alone so much could have been done, was, as if in revenge, seriously damaged by the invader, and the tunnel was left nearly filled with mud. Nine-tenths of those who professed to know anything of the subject, then considered the case desperate, and the works were indeed abandoned until the year 1836; but never, at least since the time of the Roman engineers, who confined him to his present width by their artificial embankments, had Father Thames so determined a general to oppose him as Father Brunel. Armed with a new and more powerful shield, in design a masterpiece of ingenuity and contrivance, and executed in the best manner by Messrs. Rennie, the engineer and his companions renewed the attack; and although twice afterwards beaten back and obliged to surrender possession, he has at last succeeded, and may now, I think, bid defiance to the enemy. It was my duty, as the engineer consulted by the treasury, to visit the works on several occasions, and I can therefore certify to the difficulties and indomitable courage of our veteran member, which never failed him, for the notes which he despatched to four individuals (of whom I was one) on the occasion of irruptions, read as if he were rather pleased that the event had taken place; as if he had gained a victory rather than suffered a defeat; resembling in this respect the bulletins from other great generals, who have not however always been so successful in recovering their misfortunes. The difference might be that Sir Isambard had a Wellington, not to oppose, but to aid him. But, seriously, looking at the Thames tunnel entirely in an engineering point of view, we cannot but be proud of the work, and pleased to have the opportunity of congratulating Sir Isambard Brunel on the result of sixteen years (eight of which he spent on the spot) of hard mental and bodily labour. I know no other man who would have so worked, or if he had, could have so succeeded. France, his native country, has reason to be proud of him, as England, his adopted country, is. To Mr. Armstrong, Mr. I. K. Brunel, Mr. Beamish, and Mr. (now Professor) Gordon and Mr. Page, who were successively the assistant engineers, great credit is due; and Sir Isambard has always spoken with satisfaction of their services and of the perseverance and courage of the men, many of whom stood by him in his greatest need as if the merit were to be theirs.

Electric Telegraph.—Having said thus much on the Tunnel, I am induced not to pass over unnoticed Professor Wheatstone's application of electricity for telegraphic and other purposes, considering it strictly within our province, not only from its nature, but its application to railroads and similar purposes. And as respects utility (if there be use in despatch), we need have no apprehension on that account. The velocity of Wheatstone's messenger has reached a maximum, which can safely be said of but few human things, and we ought to be satisfied, as we know that the speed is about 170,000 miles per second—that therefore a message could go to Bristol or Birmingham in $\frac{1}{1400}$ of a second, or round the globe, if wires could be laid for its travelling upon, in one-sixth of a second. The messages upon the Blackwall railway, upon part of the Great Western railway, and some other railways, are carried at this extraordinary rate. The bells in the House of Commons are rung by it, and its uses are extending. Its superiority for telegraphing appears obvious. Professor Wheatstone informed me some years since that by his machine for measuring the velocity he made 10,000 000 of miles per minute. I had named 10½ millions, being the velocity of light —my opinion, erroneous perhaps, having long been, that solar light is a modification of electricity, an hypothesis that seems to dispense with the necessity for the doctrine of latent light, which Professor Moser has introduced to account for his late elegant discoveries; but this is too wide a field to enter on now. My object is to express how much I think the profession and the country are indebted to my highly gifted friend, who has entered upon his important labours with a zeal worthy of the cause, and a success that holds out the hope of ample reward; for I feel convinced, that great as the recent discoveries in electricity or photography are, they are but an earnest of what is to come; that riches are to be extracted from these recently opened mines, of which we have not at present the most distant notion. Unfortunately miners cannot work without tools, and they cannot always, from their own resources, command them. France has, by rewarding Daguerre, and giving, so far as she could give, his inventions as a free gift to the world, set a noble example. I have not heard that Wheatstone has had any public aid in prosecuting his researches; but with our own honorary member as premier, we may depend that the government of this great country will not be indifferent to a matter which involves so much of practical utility and at the same time national glory.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

Feb. 6.—William Tite, Esq., in the chair.

Mr. Morris read a paper on *Ripon Cathedral.*

Mr. Papworth read a paper explaining the method adopted by him in 1829, to confine the lateral walls, then inclining outward of Trinity church, on Clapham-common. Upon a survey of the building, it was discovered that the brick footings of the walls of the church and tower, were built upon a continuous 4 in. yellow fir planking, containing much resinous matter, and abounding with large knots. In the first instance the trenches were not dug perfectly level, and the bottom course of brickwork was laid dry, thence much of the trench was in winter, subject to wet, and at all times to some moisture. In some parts, particularly the north west angle of the tower, and west staircase, the timber was probably never dry: the nature of gravel, (absorbing moisture freely) upon which the walls were built, of course admits damp air, and the timber is proportionably subject to the decay common to wood when so circumstanced.

The footings were first examined from the vaults, when the timber beneath the brickwork was found to be in such a pulpy state generally, excepting at the knots and closely adjacent fibres, that the walls, both of church and tower might really be said entirely to depend on the latter for support; with the addition of the adhesion of the materials and the strength contributed by occasional cross walls. The planking was very soon removed, and York stone steps and proper underpinning substituted.

Although portions of the church walls, from the parapets down to the plates receiving the gallery floors were leaning outwards, it was found that all beneath was nearly upright; of course this led to an examination of the ceiling, in which, at about the middle, a wide crack appeared running from the west towards the east end. On examining the roof, it appeared that the fissure, and the overhanging of the walls was caused by the pressure outward of the principal rafters, and chiefly on the south side of the church. This pressure outward had disjoined the tie beams, which had been scarfed in no very judicious manner in the middle, (the church being about 59 ft. wide) the scarfing was merely bound together by slight iron bands, and thin iron ties, depending on staples at their turned up ends and some spikes to restrain the lateral thrust; which force had almost wholly disengaged these contrivances, and amply accounted for the effects observed. The roof is of a mixed character uniting the king-post and queen-post arrangement. The queens were framed into the upper rafters, and those rafters, the tie beam and the king-post united and made a roof independent of the other timbers; the usual straining beam between the heads of the queen posts being omitted. The disarrangement of the timbers of the roof, by settlements common to them, and the displacement caused by the thrust, made it proper to prepare for the operation, of drawing the separated scarfed ends of the tie-beams something closer; it not being intended to give very much further effect to the power contemplated, because it might have produced injury to the entire roof, and to the upper part of the walls, the gutters and slating—at least it was considered injudicious to risk so much probable damage.

The object was only to prevent a greater separation of the tie beams at their scarfings, to stop any further thrust to the walls; and it appeared that, by drawing the lower ends of the queen-posts nearer to each other, each having a tendency to urge back its moiety of the tie beam towards the centre, that much might be done, and at no great expense. It being found that the queen-post mortices in the tie-beam were far from being filled by the tenons of the queens, and that to draw them much out of the perpendicular, might produce a further and serious disarrangement of the timbers above. To keep the queens upright, and therefore nearly parallel to each other, the timbers were bolted together through the heads of the queens, through the struts, and through the middle of the king-post; and iron blockings, intended to oppose any movement more than desirable, were carefully fitted and bolted to the top of the tiebeam at the foot of each queen-post. The application of iron rods having powerfully threaded screws and ample washers and nuts, was of course a matter of easy accomplishment, and when put into operation, there would evidently have been no difficulty in bringing the ends of the timbers into close contact: but, as above stated, there was no wish to effect much more than full security; and they were only drawn together enough to close in part, the fissure in the ceiling. As will be evident on reflection, this operation of drawing together the posts might, without due care, have left the tie beams without any check to their tendency to sag, and it was therefore found proper, at the time the iron blockings were fixed on to the top of the tie-beams, to saddle on them iron straps, bolted well through the tie-beams.

The authorities of Clapham church, not doubting the stability of the edifice, directed, in October last, the execution of two additional galleries for about 150 children, when the consequent scaffolding afforded the opportunity of a close examination, and it was very satisfactory to observe that the operation has been completely successful, and that no settlement, nor spreading of the roof, nor further overhanging of the walls, has taken place.

Feb. 20.—T. L. Donaldson, Esq., V. P., in the chair.

Mr. Godwin read a paper on *Church Building*, which is given in another part of the *Journal* for the present month.

C. W. Wooley read a paper on the *Walhalla*, which we propose to give next month, with engravings.

LICHFIELD SOCIETY FOR THE ENCOURAGEMENT OF ECCLESIASTICAL ARCHITECTURE.

The first annual meeting of the members of this society was held on the 5th of January, at the Diocesan School Room, at Lichfield, and, was numerously attended. The chair was taken by the Rev. Prebendary Gresley, upon the motion of the Hon. and Very Rev. the Dean of Lichfield. The report of the Proceedings of the committee for the past year was read by Richard Greene, Esq., F.S.A., Hon. Sec.; and we are glad to perceive thereby that, although in its infancy, and with but small present available funds, the society is stimulating the desirable object of church restoration upon correct principles, and is, in conjunction with sister societies, strenuously resisting the gradual destruction of our venerable churches by time, and that greater innovator, ignorance. We trust the day is arrived when the beautiful remains of those fabrics raised by the piety and skill of our forefathers, and venerated by us, will be rescued from the tender mercies of agrarian churchwardens, and own the fostering care of better guardians.

The report was followed by an address from the Chairman, in which he set forth, in his usual plain and felicitous style, the leading characteristics of Gothic architecture, from the earliest period to its abasement in the reign of Elizabeth, and offered some strictures upon the cheap church building of modern times.

Thomas Johnson, Esq., followed the chairman, with some most excellent practical remarks upon the care to be observed in effecting what are termed restorations. He admitted the great utility and advantage to be derived from the combined talent and enquiries of such societies; but, as a practical architect, he held out a warning to their members to remember the ancient adage, "*Ne sutor ultra crepidam.*"

The proceedings were concluded by the honorary secretary, Richard Greene, Esq., who read a paper upon the sculptures of Norman architecture, in which he advanced the somewhat startling opinion that our earliest Christian church embellishments are essentially pagan, and of idolatrous origin. He supported the proposition with great ingenuity, and most interesting facts, elucidating the paper throughout with numerous drawings.

METROPOLITAN IMPROVEMENT SOCIETY.

On Wednesday evening, 22nd ult., a meeting of the Metropolitan Society was held. Mr. J. Ivatt Briscoe in the chair. The chairman congratulated the meeting on the attainment of one of the principal objects of the society —the appointment of a government commission to prepare a comprehensive plan of metropolitan improvement. From a letter in the hands of the secretary of Sir Robert Peel, it appeared that the new commission had commenced its labours by inquiring into the expediency of an ordnance survey and map of London upon the largest scale, and it was understood that the commission was now engaged in considering the various plans proposed for an embankment of the Thames. Mr. Martin, the painter, said, that for fourteen years he had been engaged in promoting the two-fold object of throwing open the banks of the Thames, and of converting the contents of the sewers, now flowing into the river, to agricultural uses.—Mr. W. E. Hickson observed, that some idea of the pecuniary value of the liquid manure, now permitted to be lost, might be formed from the fact, that in Paris a new contract had recently been signed, by which the contractor agreed to give the city 22,000*l.* for the contents of the cesspools of Paris. Mr. Fowler observed, that as numerous private interests would be affected by an embankment of the Thames, it was very important to watch any proceedings relating to this object, in order that the public interest should not be sacrificed. Mr. W. Lindley was anxious that the new commission in considering any plan for the embankment of the north side of the river, should inquire into the practicability of connecting it with the Essex road by means of a new and broad street running from Aldgate to the Thames, so as to form a practicable carriage thoroughfare from the west to the east of London, which now could scarely be said to exist.

MODERN CHURCH ARCHITECTURE.

A very clever little periodical, *The Ecclesiologist*, published by the Cambridge Camden Society, has already done much good in counteracting the churchwarden barbarisms that have been too often committed in many of our churches; it is also creating a taste among the clergy for Gothic architecture, which will ultimately be of great service to the profession, and act as a counteraction to the selection of inferior designs by "Building Committees." The selection is frequently governed by favouritism, and much oftener by the want of true taste in those who are appointed to select the designs out of probably 50 or 60 that may be laid before them. We quite agree with the following hint on modern church architecture, and consider that too much attention and money is bestowed in highly finishing the stone work, carving, and other ornaments, when frequently rough scabbled stone work will produce a more pleasing effect than the highly wrought stone, and be done at one-half the expence, consequently it may be used less sparingly than it now is; in fact, very frequently the whole church may be built or faced with such stonework as cheap as with brickwork.

"How often do we," says the *Ecclesiologist*, "see a simple village church, consisting, it may be, of low and rough stone walls, surmounted, and almost overwhelmed, by an immense roof, and pierced with some two or three plain windows between as many bold irregular buttresses on each side, or having a short massive tower placed at one corner, or in some seemingly accidental position, which nevertheless every one confesses to be as picturesque and beautiful and church-like an edifice as the most critical eye or the most refined taste could wish to behold. And just such another church could be built, perhaps, for seven or eight hundred pounds; while a modern early-English design, with all its wouldbe elegancies of trim regular built buttress, tripellancet, and curtailed chancel, would contain no more kneelings, cost more than twice the money, and look like a 'gothick factory' after all. And why is this? Because a lofty tower must be built instead of a simple unpretending chancel; or because one-half of the money is expended first in procuring, and then in smoothing and squaring, great masses of stone, or in working some extravagant and incongruous ornament, so that cast-iron pillars must be placed in the interior instead of piers and arches; whereas the small and rude hammer-dressed Ashlar, or rubble work, of the ancient model, has a far better appearance, and allows a larger expenditure where it is most wanted, in procuring solid, handsome, and substantial arrangements for the interior."

EDGE'S IMPROVED GAS METER.

Fig. 1.

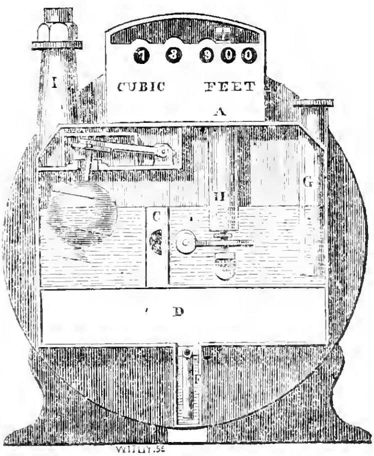


Fig. 2.

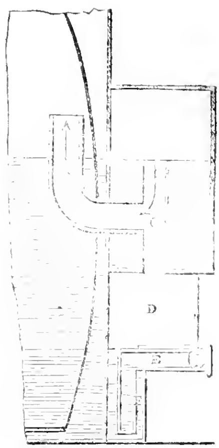

Considerable excitement has lately been raised respecting the gas meters, in consequence of Mr. Flower issuing a pamphlet accusing the gas companies of defrauding the consumer by the false registering of the meter, occasioned by filling the meter above the proper level with water; when that is the case, he contends that the meter is registering water instead of gas, whereby the consumer is suffering considerable loss. This did appear to us a very serious charge, and in this age of improvement we felt surprise that this "false registering" could not be avoided, and that there was no scheme to adjust the water in the meter to the proper level, so that the meter should correctly register the exact quantity of gas consumed. Upon making some inquiry upon the subject, we very soon discovered that a meter, combining the requisites just alluded to had been invented and patented by Mr. Botten, and another by Mr. Edge, the well-known manufacturer of gas meters and fittings; but we consider the meter of the latter the best, as it combines other improvements. We have, therefore, much pleasure in presenting to our readers a description and engravings of Mr. Edge's meter, which appears to us to be as perfect as a wet meter can well be.

Fig. 1 is a front view of the meter, with the outer casing removed to show the interior, and Fig. 2 is a cross section of the front portion of the meter. A is the improved index. B, patent lever valve. C, syphon pipe. D, waste water cistern. E, F, hydraulic sealed outlet to allow the accumulation of water in the waste water cistern to be drawn off upon the removal of the plug at E. G, tube for filling the meter with water, which dips into the water, and consequently prevents the escape of gas. H, shaft and apparatus connected with index. I, inlet tube through which the gas passes into the meter through the valve B, thence down the pipe C, and again up into the interior or drum of the meter, as shown by the arrows in the section Fig. 2. Thence through spiral chambers within the wheel, as it revolves, to the outside of the wheel, and escapes into the surrounding chamber, and out at the outlet tube, on the top of the meter, at the back of the index box A. As the gas passes through the spiral chambers, the pressure of the gas causes the wheel to which they are attached to revolve, and with it its axis, which is prolonged and passes through to the front box, where, by means of an endless screw on the prolonged end of the axis working into a toothed wheel keyed on to the lower part of the shaft H, and a pinion on the upper part of the shaft, sets in motion the clock-work of the index, which shows the quantity of gas that passes through the meter.

There are several important improvements combined in Mr. Edge's meter, which we shall proceed to describe, the first and most important is an arrangement to prevent too much water being put into the meter. This is accomplished by the patent syphon C, and the waste water chamber D, the value of which cannot be over estimated; for, in the first place, it removes the only dangerous part of the meter, viz., the outlet from the syphon pipe, which is now sealed off; in the second place, it prevents the fraudulent abstraction of the water, to the serious injury of the company: and thirdly, it obviates the only tenable objection to the meter alluded to in Mr. Flower's pamphlet, that is, the accumulation of the water, by which the consumer is deprived of his full measure. The top of the syphon pipe C being placed on a line with the water level, every surplus drop must pass down it into the waste water box D, thence into the pipe F below, and when the plug is removed, it rises up the pipe F, and passes out at the orifice E; and as this pipe is bent downwards, it must always present an hydraulic joint to prevent the escape of any gas that might accumulate in the syphon C, and which, by the construction of the old meter, would escape when the plug was removed. Provided too much water be collected, it would prevent the influx of any gas, consequently it must be at once detected; the consumer would then have only to unscrew the plug E, and allow the water to run off, which may be done without the least danger. It will be observed that there is only one outlet screw, E, instead of two, as in the common meter.

The second improvement is the patent index A, which enables the consumer to ascertain the quantity of gas used with ease and certainty. The complexity of the old method, which consists of 3 dials with the movements of the hands or pointers, has been the occasion of very frequent mistakes and misunderstandings, even with the inspectors, and amongst the consumers has created a feeling of doubt and distrust injurious to the advancement of the meter. In the improved index, the figures are made to revolve instead of the hands; and as the only one figure required on each plate (to denote the number of cubic feet consumed) can be seen at a time, *no mistake can arise*, so that both parties will be satisfied. A reference to the engraving cannot fail to establish its great superiority, and show how the quantity may be read off as 78,900 without the chance of error.

The third improvement is the patent lever valve, B, the object of which is to prevent the numerous complaints of the consumers, and the very heavy losses to the companies, by the lodgment of the old valve, consequent on the corrosion of the guide wires; this lodgment can rarely, if ever, be proved by ocular demonstration, as the slightest movement will cause the valve to fall into its seat, but still it is proved daily, *and beyond all question*, by a diminished registration; and it is not the less objectionable, as an evil, for being a secret and invisible one. The lever valve completely and effectually remedies this; it also indicates a deficiency of water much earlier than the old valve, and the shield protects it at once from any sudden rush of pressure; it may, in fact, be considered perfect in its action, and unassailable on every point.

DRAWING SCALES.

Mr. Drake, of Elm-tree-road, St. John's Wood, land-surveyor, has obtained a patent for making scales for laying down plans, of the same paper as that on which the plan or drawing is laid down. The scales are intended to accompany the plans to which they belong, and being of the same material, they consequently expand or contract, by changes of temperature, in exactly the same proportion as the plan. The paper to be drawn upon is mounted on linen or cotton, by means of India-rubber cement, and, on a strip of it the scale is made. The under surface of the straight edge or holder, by which the scale is held, whilst being used, is rabbetted, and covered with a piece of paper or linen, so as to form a space for the reception of the scale; and the off-set scale, used with it, has a small metal frame at one end, which works against the edge of the holder.

GALVANIZED IRON.

About five years since a patent was taken out in this country, by M. Sorel. for the purpose of galvanizing iron, by a process of coating it with zinc, in a similar manner to tinning, but for some cause, we believe a dispute among certain capitalists, this patent has been allowed to remain in abeyance, during which period, it has been in considerable use in France, and is, at the present time, we understand, extensively employed by the French government. It is now taken up in this country by some spirited individuals, who have established large works in London for zincing iron to any extent. The process may be applied to both cast and wrought iron in any form.

"The effect of zinc in protecting iron from oxidation," says Professor Graham, "has been known to chemists for some time. When these two metals are in contact, an electrical or galvanic relation is established between them, by which the iron ceases to be susceptible of corrosion by dilute acids, saline solution, or atmospheric humidity. It was found in experiments lately conducted at Dublin and Liverpool, that small pieces of zinc attached to each link of a chain-cable were adequate to defend it from corrosion in sea water. The protection was observed to be complete even in the upper portion of the iron chains by which buoys are moored (and which, from being alternately exposed to sea water and air, is particularly liable to oxidation,) so long as the zinc remained in contact with the iron links. The protecting influence of the zinc could not be more certainly secured than in the articles prepared by the patent process, the iron surface being uniformly coated over by that metal. In trials to which I have had an opportunity of subjecting them, the iron escaped untouched in acid liquids, so long as a particle of the zinc covering remained undissolved. The same protection is afforded to iron in the open atmosphere by zinc, with a loss of its own substance, which is inappreciably minute. The zinc covering has the advantage over tinning, that, although it may be worn off, and the iron below it partially exposed, the iron is still secured from oxidation by the galvanic action, while the smallest quantity of zinc remains upon it; whereas tin, in common tin plate, affords no protection of this kind, and not being absolutely impermeable to air and moisture, the iron under it soon begins to rust in a damp atmosphere. The simplicity and perfect efficacy of the means employed to defend iron from the wasting influence of air and humidity in this process of *zinc tinning*, certainly entitle it to be ranked as one of the most valuable economical discoveries of the present age."

DR PAYERNE'S PATENT FOR PURIFYING AIR.

An abstract of this patent appears in the *Mechanics' Magazine*; it is granted to W. R. Vigers, Esq. of Russell-square, on behalf of Dr. Payerne, "for a mode of keeping the air in confined places in a pure or respirable state, to enable persons to remain or work under water and other places, without a constant supply of fresh atmospheric air."

The first thing claimed and specified is the depriving the atmosphere in confined places of the carbonic acid gas which it contains, produced from respiration or combustion, by means of quick lime and caustic alkali, or of the lime alone, which is to be dissolved in eight times its weight of water. The air in the apartment is to be passed through this caustic solution by a pair of bellows, the nozzle of which reaches nearly to the bottom of the vessel containing the lime and water. The vitiated air thus coming in contact with the lime, the carbonic acid gas is absorbed. It is calculated that one cubic foot of atmospheric air must be purified for each person per minute.

2. The patentee claims the restoring the requisite quantity of oxygen, to supply the place of that consumed; which oxygen is to be procured from the chloride of potash, or driven off from the peroxide of manganese by means of heat, into the apartment or allowed to escape from vessels into which it may have been previously compressed.

3. The patentee claims further, the purification of the air contained in the diving bell, by the process described in claim 1, and the restoring the requisite proportion of oxygen from a vessel attached to the diving-bell, into which the oxygen had been previously compressed; also the allowing the escape of atmospheric air, which had previously been compressed several atmospheres, into two compartments, one of which is situated at each end of a diving bell, somewhat resembling a boat inverted, the centre one being occupied by the diver or workmen, who may, by means of stop-cocks, regulate the supply according to their wants.

The specification is of extraordinary length, filling no less than ten skins of parchment, but the above extract contains all that is material in it.

BITUMINOUS STREET PAVING.

Notwithstanding several unsuccessful trials of bitumen in the paving of carriage-ways, as in the Vauxhall Road some years ago, and more recently in Oxford Street, the Parisian Bitumen Company is at this time engaged in paving the square space opening into Hungerford Market, at the bottom of Hungerford Street, Strand. As this place is not subject to the same kind of wear and tear as a street through which a rapid traffic is constantly passing, it is possible that the bitumen may here answer better than in former trials, and in any case it may interest our readers to know the method pursued by the Company in their present operations.

The bituminous pavement consists of blocks a foot square and 6 inches in depth. These block are composed of an artificial bitumen and angular broken stones, forming a concrete of considerable tenacity. When the granite stones of the old pavement had been taken up and removed, a surface with a considerable convexity in a transverse direction was prepared to receive the bituminous blocks. These are then laid down in straight lines longitudinally, and breaking joint transversely. The blocks are not placed close together, but with a space betwen them of about one inch all round each block. This space is left for the purpose of being filled with melted pitch in order to fix the blocks in their places. These spaces or joints between the blocks are filled in with pitch at several different times; but when the pitch joint is only 2 or 3 in. in depth, the blocks are quite immoveable. When the first thickness of pitch has become quite solid, the joints are filled with the same substance up to the top, and before the top surface of the joint has time to set, a workman sprinkles it over with a sharp, yellow, large grained sea sand, which sets firmly in the pitch. The pavement, when finished, presents the appearance of an ordinary stone pavement, except that the blocks, instead of ranging in straight lines transversely across the road, are placed in straight lines in a longitudinal direction. We can see no good reason for this deviation from the old practice, while on the other hand it has obviously one great defect, namely, that the water falling on the surface is checked in its escape to the sides at every course of stones, and thus the surface of the roadway must be kept constantly wet. The unbroken transverse lines of joints in an ordinary pavement, answer the useful purpose of minute channels to convey the water off to the sides. It may be said that the bituminous surface will prevent the penetration of water, and that the water lodging on the surface is of no consequence. We cannot agree in this, but consider on the other hand that for this very reason bituminous pavement should always be laid with a slope in some direction, so that the water, which can only otherwise escape by evaporating, may drain off it as fast as it falls.

MISCELLANEA.

Stockton.—The bridge to substitute the Stockton Suspension Bridge is now in progress; two of the piers are completed—one on each side of the stream; and the gangways and travelling cranes are erected. Mr. Grainsley of Newcastle is the contractor for the masonry, and Mr. Kitchen of Darlington, the contractor for the iron work. The foundation requires piles 50 feet long, and a 10-horse engine with a ram of 18 cwt., and three men to drive them. The stone piers are dressed in rockwork, six feet broad at top; the span is 83 feet 6 inches between the piers; the roadway is to be carried by cast iron bearers about 3½ feet deep. The site is about 100 feet above the suspension bridge, up the stream or to the west of it. It is not certain whether the suspension bridge will be taken down, or used as a turn-out for empty wagons.

Middlesborough Dock.—This dock was completed in the early part of 1842, and ships were admitted on the 12th of May in that year, and the shipment of coals has been carried on regularly in the dock since that time. It has an area of nine acres of water surface, and is entered by a commodious channel rather more than a quarter of a mile in length, leading from mid-channel of the river Tees. The entrance lock is 132 feet long, and 30 feet wide; the depth on the sill averages about 18 feet at spring tides, and 15 feet at neap tides; and the coping is 21 feet above the sill. The bottom of the dock is three feet under the level of the sills; the sides of the dock are sloped and paved with stones at the water's edge. For the shipment of coal there are 10 staiths or "drops," at each of which coals may be loaded at the rate of 5 keels, or 105 tons per hour. Ballast is taken out at a very low rate, by means of cranes situated at different places on the river banks. The branch railway leading from the Stockton and Darlington line, which communicates with the dock, is situated on the south side of the town of Middlesborough; it terminates in 10 lines of double railway leading to the 10 drops. The raised platform is covered by three diverging lines of railway, it comprises an area of 15 acres, and affords standage room for 1,200 loaded wagons, or more than 3000 tons of coal, besides ready means of egress for locomotives with their trains of empty wagons. Unfortunately the lock entrance has been constructed too narrow for steam tugs to enter, of which there are about 20 from 25 to 50 horse power. The channel from Middle Tees is very much liable to silt up, and requires constant dredging. Mr. Cubitt was the engineer, and Mr. Turnbull the resident engineer, and Mr. Briggs the contractor.

Lower Shannon Improvements, Ireland.—The works at Banagher are contracted for by Mr. William M'Kenzie, and consist of deepening all the fords in the river from Killalo to Athlone, either by dams and excavating, or by dredging. Two 12 horse dredgers are employed, and two weirs are to be constructed, 1100 feet long each, across the Shannon; also a lock 170 feet by 40 feet, and 8 feet rise to pass an 80-horse steamer; likewise a stone bridge at Banagher of 6 arches 60 feet span, and a 40 feet swivel bridge on one side to pass the steamer through. The works are under government, and are expected to be completed in the ensuing summer.

The Duke.—A new steam vessel, of 765 tons burthen, was launched at Liverpool on the 25th of January, having been built by Mr. Thomas Royden for the East India and China trade.

ALEXANDRIA.—We have already informed our readers, says the "*Ecclesiologist*," of our (the Cambridge Camden Society) engagement to supply designs and working drawings of a new church to be erected at Alexandria. These have now been completed by the architect, Mr. Salvin, and will be dispatched by the earliest post to their destination. As it may be interesting to many, and especially to the absent members of the Camden Society, to have some account of the form and plan of this church, we shall here subjoin a brief description of it for their information. The entire length of the church externally is 128 feet by 50 feet in breadth (exclusive of a north and south porch). The plan comprises a full and spacious chancel, 40 feet by 18 feet internally, and a nave and aisles, 78 feet by 40 feet; and a tower with a lofty spire is to be added, if funds can be procured, in the place of the south porch. The chancel is raised by three steps, and is furnished with all the proper appurtenances of stalls, priest's door, credence, sedilia, and piscina. The seats in the nave are ranged in four parallel rows facing the east, there being a passage of 5 ft. 9 in. in the centre, and one of 2 ft. 6 in. in each aisle next to the piers. The seats are, of course, all open. The west front, adapted from that of Llanercost Abbey, exhibits a beautiful façade made by the nave, which is terminated by a high-pitched roof with a gable cross between two large pinnacle turrets, and has below a lofty arcade pierced with two lights, and the two aisles, each of which carries a separate gable with a cross, and a single lancet light. To this front the north porch and southern tower will add great breadth and diversity of effect. The chancel, nave, and aisles will be vaulted; and the clerestory lighted by a circular window in each groined compartment. The aisles are lighted by single lancets between buttresses with pedimented heads and set-offs. The east end will have a peculiarly beautiful effect, from a richly arcaded triplet with a wheel window above, and from the lofty gables of the chancel, nave, and aisles, all of which will be surmounted with crosses, and are similar in design to the west end. The sides of the chancel contain three bays, each of which is arcaded of three, with the central arch pierced for a lancet light. Every portion of this church has been designed in strict conformity with ancient models.

LANCASHIRE.—We have been permitted by the architect, Mr. Sharpe, of Lancaster, a member of our Society, to inspect the plans and working-drawings of a new church which he is now erecting at Knowsley, in Lancashire. There are many points in this design which deserve great commendation, and as a whole, it may safely be pronounced a most successful example of modern church building, although some of the arrangements appear to us liable to serious objection. The church is of the early-English style, and consists of a good chancel, nave with aisles, and tower with broach spire at the west end. There will be no galleries, and the ground-floor alone will accommodate 400 worshippers. There is a well-defined clerestory, supported by beautiful clustered piers and arches, and surmounted by a very fine high-pitched roof, the trusses of which spring from triple-shafted corbels, with floriated capitals. The walls of this church are somewhat too thin to allow of the proper internal splay of the lancets, and appear to us to be too much and too *regularly* pierced. Thus each side of the aisles and clerestory exhibits an equal number of lancets, placed exactly opposite to each other. We should have preferred single lights in both positions, for a church *should be dimly lighted;* or the clerestory might have had foliated circles (a beautiful early-English feature, which we wonder is not more frequently introduced), and the aisles plain two-light windows with circles in the heads. There is too much sameness in so great a number of lancet windows. The nave roof might have been carried up to the belfry windows with better effect. The tower is very good, and has nothing to which we can object, excepting a number of small trefoil apertures which are intended to light the staircase, but which should rather have been plain oblong slits in the wall. There is, we suspect, but scanty ancient authority for such ornaments, unless in very magnificent towers, and they appear singularly inappropriate when placed just below the point where the broach meets the top of the tower, since this part ought especially to convey the idea of strength and solidity. Small apertures, however, of this description occur in St. Mary's tower, Stamford. The northern porch (we should have much preferred a southern one, or at least a southern door should have been added, as at Woodton, Norfolk; Irnham, Lincolnshire; and of later date, Grantchester and Chesterton churches, near Cambridge,) has too large a doorway, and its roof does not meet that of the aisle in a pleasing manner. The west door would be very good if the mouldings were less meagre and ornamental. A tower doorway of this style should be very deeply recessed, and have a great display of arch moulding. The details in general are very good, and have the rare merit of being at once extremely correct and varied in form. We have several grave objections to make against the internal arrangements. There is no central passage to the altar; but the space which ought to have been left for this purpose is occupied by seats for children. The tables of commandments, creed, &c. are placed in an arcade above the chancel arch—a modernism which we consider altogether inadmissible, to say nothing of its bad effect. We should be inclined to carry the chancel arch considerably higher. The organ is at the east end of the north aisle; it should rather have been at the west, and a window at the east end. The font is too nearly the centre of the nave; its correct position is by the west pier nearest to the porch. Upon the whole, however, great praise is due to this design; but we deeply regret to observe that some of the internal details are to be executed in *plaster*. We had much rather that they had not been attempted at all. Under the chancel is a vaulted crypt, and above it we observe with no great satisfaction a contrivance for warming the church with hot air.—*Ecclesiologist.*

NEW MILITARY CHURCH AT WINDSOR.—The last stone of the spire of the new military church was laid on Friday morning, Dec. 30. The first stone of this building was laid on the 4th of April last. The church is built of white brick and Bath stone, and its architecture is pure Gothic: it is in the form of a crucifix, having two large transepts for the accommodation of the military and the one at the west end for the children. These galleries are calculated to contain between 400 and 500 persons. A certain portion of the church will be set apart for the accommodation of the soldiers' wives. The body of the church will be fitted up with beautifully carved oaken benches, by which, whilst this arrangement will afford a great number of sittings, will present a light and elegant appearance at a much less cost than the erecting of pews. In addition to the accommodation afforded to the military, there will be about 1,000 sittings for the inhabitants of Windsor and Clewer. The principal feature of this church is the beautiful tower and spire, the tower being nearly 100 feet high, and the spire, of Bath stone, rising 48 feet, surmounted by a vane. The cost of this edifice will be about £10,000, nearly one-half of which is already subscribed, Her Majesty and Prince Albert being large contributors. The building is designed by Mr. E. Blore, and when complete will form a magnificent object from the Castle and surrounding neighbourhood, being one of the most beautiful designs on this side of the metropolis. The whole of the plans have been carried out with great accuracy by Mr. J. B Heard.

THE PRINCE ALBERT.—A new iron built steamer of the above name, has been making several trips up and down the river Thames, trying her speed, which proves to be very superior, and equal to our fastest steamers; at present she has exceeded the speed of all that she has been able to compete with, even the far famed "Railway." She is an iron built vessel, the deck beams are also of deep angle iron, to which the deck planks are bolted down: her length is 155 ft. between perpendiculars; extreme breadth 19 ft. 6 in.; draught of water when loaded, 4 ft. 6 in.; length of saloon, 36 ft., fore cabin, 36 ft., engine room, 26 ft. The engines are of the direct action principle, constructed by Messrs. Braithwaite, Milner, and Co., and are a beautiful specimen of workmanship, and occupy an extremely small space. The diameter of steam cylinders, 40 in.; length of stroke, 40 in.; nominal H. P. of the two engines, 110 horses, with 32 revolutions per minute, diameter of paddle-wheels, 17 ft. 6 in.; breadth, 9 ft.; space occupied by engines, 10 ft. 8 in. in the breadth, and 6 ft. 6 in. in the length of vessel. The engines are constructed with two piston rods to allow the piston in the centre to be hollowed out, that the cover may be dished in a similar manner, to allow the connecting rod and cross-head to descend partially into the cylinder, that the length of connecting rod may be as long as possible, which is equal to three times the radius of crank, or five feet; the air-pump and feed-pump are worked from either end of the cross-head; the boilers are tubular, on *Spiller's* construction. The time occupied in the passage from Blackwall to Gravesend, the day we were on board, was 1 hour 13 minutes, with a slack tide, but against the wind, and 1 hour 5 minutes returning.

TEMPERADOR.—This steam vessel is the first of a pair built for the Post-office service in the Brazils, which business is performed by a private company. She was built by Messrs Fletcher, Son, and Fearnall, from the designs of Messrs. Ritturden and Carr. (Mr. Ritturden is the surveyor of shipping to the honourable the East India Company.) She is a very superior specimen of Thames building, and her arrangements and cabin fittings are in a style of extreme neatness and comfort. The length between perpendiculars, 151 ft. and over all 169 ft. 6 in.; breadth, extreme to a 3 in. plank, 24 ft.; depth in hold 14 ft.; burthen, old measurement, 418 tons; her draught of water, loaded, is 9 ft. 3 in. forward, and 10 ft. 2 in. aft. She has two engines, of the collective power of 140 horses, constructed by Messrs. Miller, Ravenhill, and Co. They are finished in a superior manner, and work most satisfactorily; the speed of the vessel in the river, with every thing on board, and the coal boxes full, was $10\frac{1}{2}$ statute miles per hour. The vessel left London on the 5th ultimo for South America, and performed the distance from Blackwall to Falmouth Harbour in 42 hours, consuming from 9 to $9\frac{1}{2}$ cwt. of coal per hour, with the steam up to $5\frac{3}{4}$ inches, and the barometer standing at $27\frac{1}{2}$ inches; the engineer reports that he had plenty of steam, and the firing very easy.

THE BENTINCK.—This fine steam vessel, which has been for some time building as a companion to the *Hindostan*, was launched on the 25th of January, from the yard of Mr. Wilson, at Liverpool: she is proposed to be nearly a fac-simile of the *Hindostan*, and was moored in the Trafalgar Dock, to be completed, and to receive her engines, which are being constructed by Fawcett and Co.

THE ROYAL MAIL STEAM SHIP "HIBERNIA."—Another superb ship has been added to the fine fleet of steamers belonging to Cunard's line, running between Liverpool and Halifax. She was built at Greenock, by Messrs Steele and Co.; burthen 1350 tons, length between perpendiculars 218 feet, and depth of hold 24 feet. Her engines were constructed by Mr. Robert Napier of Glasgow, and are of the nominal power, the piston travelling 220 feet per minute, of 550 horses collectively, the diameter of cylinders is $77\frac{1}{2}$ inches, and length of stroke 7 feet 6 inches, the paddle wheels 30 feet 4 inches diameter.

ELECTRIC TELEGRAPH.—Mr. Cook, the joint patentee with Professor Wheatstone, of the voltaic telegraph, has been commissioned to lay down a line from the Paddington station of the Great Western Railway to Windsor Castle, and carry it thence to the Parliament houses and Buckingham Palace. The effect of this will be, that on important occasions, when the sovereign may be at Windsor, any intelligence of extraordinary interest can be transmitted to her Majesty in a second—nay, in less time. The voltaic electricity which governs the motion of the telegraph, travels at the rate of two hundred and eighty-eight thousand miles a second. This has been proved by the delicate instrument invented by Professor Wheatstone. The new and most singular arrangement will be of great value in connection with the public service. When cabinet councils sit on momentous questions, her Majesty can be acquainted with the result of their deliberations as instantaneously as if she were present. When the Queen presides over the meetings of her ministers in person at Windsor, it not unfrequently happens that information on a particular subject may be required from the departments in London; and hitherto, when this has been the case, it of course became necessary to send an express to town to obtain what was called for, before the business could satisfactorily proceed. Now it, in most cases, will be procured while the council is sitting, and, indeed, in the course of four or five minutes, which before would have caused a delay of as many hours. This will not only be of use on great occasions, but in a common way its every-day value will be considerable. During the session of parliament, for instance, on every question of interest her Majesty can learn the division, or the progress made in a debate, one moment after the house has divided, or any particular orator has risen to speak or resumed his seat. Thus, a more rapid communication between the sovereign and her ministers for the time being will be established than has ever been known or thought of before.—*Mirror.*

The Birmingham Town Hall Organ has undergone great alterations. These consist of certain new arrangements and adaptations, founded on an extensive survey of the great organs both in Germany and Holland; and will have the effect of greatly increasing the powerfulness, and variety of this splendid instrument, the recent improvements having caused an addition of about 1200 pipes. The height of the case is 54 feet, and 40 feet wide, and, contains about 4000 pipes. The circumference of the CCCC metal pipe is 5 feet 3 inches; the largest wood pipe (the CCCC) is 12 feet in circumference, and its interior measurement is 224 cubic feet. The organ contains 63 real stops, six copulas, and has four sets of keys; the fourth is the combination or solo organ, upon which (by an ingenious contrivance) can be played any stop or stops out of the swell or choir, without interfering with their previous arrangement. There are several stops peculiar to this organ, and which are not to be found in any other; amongst them is the grand ophicleide, invented by Mr. Hill, which is distinguished by its immense power and richness of tone. The posaune is built on a large scale, and is by far the most powerful ever made. By coupling the pedals with the keys, 87 pipes are made to speak with each pedal. The bellows contain 300 square feet of surface, and upwards of 3 tons weight upon them is required to give the necessary pressure. The machinery of the organ is so very extensive, that the trackers, if placed in one line, would measure more than 5 miles.

Nankin and its Porcelain Works.—Numerous, as you may conceive, have been the pilgrimages made to the far-famed "Porcelain Tower," for the first time in inspecting any of the monuments *renommés* of this country, no disappointment has been experienced, while comparing what actually is, with what the legends of the book-makers in China describe to be. It is, indeed, a most elegant and singular structure, as remarkable for its correct proportions as for the rare material of which it is partially composed. I say partially, because the mass of building is not of porcelain, but is composed of common brick, with a facing and lining of beautiful white glazed porcelain bricks or slabs, fixed into the masonry by means of deep keys or shoulders, cast like a half T. on the brick. Its form is octagonal, and running up each of the angles is a moulding of large tiles of very fine clay, glazed and coloured red and green alternately; round each story runs a high balustrade formed of green porcelain, upon which four arched doorways open, set to the four cardinal points, the arches being elegantly turned with large glazed tiles, cast in all imaginable fancies of design and variegation of colour representing wild beasts, demons, deities, monsters, &c. It appears to be a "sight" amongst the Chinese themselves, for there are priests or bonzes attached to the building to keep it in order, who earn their consideration by distributing to the visitors lithographed elevations of the tower, with descriptions attached, and who seem to have the duty entrusted to them of illuminating it on gala occasions. This is effected by means of lanterns made of thin oyster shells, used in lieu of window glass by the Chinese, which are placed at each of the eight angles on every story, and the effect of whose subdued light on the highly reflective surface of the tower must be most striking and beautiful.—*Bombay Spectator.*

Florence.—*The Duomo.*—The grand Duke has given orders that the "Gran Duomo" of Florence shall be completed under the direction of the Imperial Academy. The dome was begun to be built in 1296, by Arnolfo di Lapo. In the works now to be commenced, the materials to be employed are marbles from the quarries of the two mountains Seravezza and Altissimo, in some respects more beautiful than those of Carrara, and they are those which Michael Angelo made use of.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM JANUARY 31, TO FEBRUARY 25, 1843.

Six Months allowed for Enrolment, unless otherwise expressed.

George Benjamin Thorneycroft, of Wolverhampton, ironmaster, for "*improvements in furnaces used for the manufacture of iron, and also in the mode of manufacturing iron.*"—Sealed Jan. 31.

William Maugham, of Newport-street, Lambeth, chemist, for "*an improvement in preparing aerated water.*"—Jan. 31.

William Barnard Boddy, of Saint Mary, Newington, surgeon, for "*improvements in apparatus and means for opening, shutting, and fastening every description of sliding and lifting window sashes, windows, and window shutters.*"—Jan. 31.

William Robinson Shaw, of Leeds, engineer, for "*improvements in feeding or supplying steam boilers with water.*"—Jan. 31.

Samuel Kirk, of Staly-bridge, Lancaster, cotton spinner, for "*improvements in machinery or apparatus for preparing cotton and other fibrous substances for spinning.*"—Jan. 31.

Charles Hancock, of Grosvenor-place, artist, for "*an improved means of dyeing or staining cotton, woollen, silk, and other fabrics, and rendering them repellent of waters and moisture.*"—Jan. 31.

Charles Clark, of Great Winchester-street, London, merchant, for an "*improved pyro-hydro pneumatic apparatus, or means of generating, purifying, and condensing steam and other vapours, and of extracting from vegetable substances the soluble portions thereof, as also the application of parts of the said apparatus to other heating, evaporating and distilling purposes.*"—Jan. 31.

James Clark, of Glasgow, power-loom cloth manufacturer, for "*an improved mode of manufacturing certain descriptions of cloths.*"—Feb. 1.

John Hill, of Manchester, machine-maker, for "*improvements in or applicable to looms for weaving carpets and various other fabrics in which raised loops or a raised pile constitute the face or the figure of the fabric.*"—Feb. 11.

Robert Hicks, of Old Burlington-street, surgeon, for "*improvements in apparatus for impregnating liquids with gases.*"—Feb. 11.

Joseph Morgan, of Manchester, manufacturer of patent candle-making machines, for "*improvements in the manufacture of candles.*"—Feb. 11.

Jonathan Badger, of Sheffield, carpenter and builder, for "*improvements in the construction of bedsteads for invalids.*"—Feb. 11.

Christopher Nickels, of York-road, Lambeth, gentleman, for "*improvements in the manufacture of fabrics made by lace machinery.*"—Feb. 11.

Thomas Ensor, of Milborne Port, glove manufacturer, for "*improvements in the manufacture of leather gloves.*"—Feb. 11.

Henry Du Bochet, of South Mall, Ireland, piano-forte tuner, for "*a new method of making pianofortes.*"—Feb. 11.

Thomas Wolverstan, of Salisbury, iron founder, for "*improvements in axletrees and axletree boxes.*"—Feb. 11.

Alfred Brewer, of Surrey-place, Old Kent-road, wire-weaver and felt manufacturer, for "*improvements in machinery for manufacturing paper.*" (A communication.)—Feb. 11.

George Ebenezer Doudney and Edward Phillips Doudney, of Mile-end, Portsea, candle manufacturers, for "*improvements in the manufacture of dip and mould candles.*"—Feb. 17.

James Boydell, jun., of Oak Farm Iron Works, near Dudley, ironmaster, for "*improvements in apparatus for retaining the wheels of carriages in the event of an axis breaking, or otherwise.*"—Feb. 17.

Henry Ross, of Leicester, worsted manufacturer, for "*improvements in combing and drawing wool, and other fibrous substances.*"—Feb. 17.

Charles Brook, of Meltham Mills, York, cotton spinner, for "*improvements in the apparatus used for purifying gas.*"—Feb. 17.

William Newton, of Chancery-lane, civil engineer, for "*an improved system of working coal mines and quarries of stone, marble, and slate, which may also be applied to the making of tunnel borings, or to other purposes of the like kind.*" (A communication.)—Feb. 20.

John Kymer, of Pontardalaw, South Wales, coal proprietor, and Thomas Hodgson Leighton, of Llanelly, Carmarthen, chemist, for "*improvements applicable to the burning anthracite or stone coal, and other fuel, for the purpose of obtaining heat.*"—Feb. 21.

Joseph Crannis and Robert Kemp, both of Southwark, furriers, for "*improvements in wool paring.*"—Feb. 21.

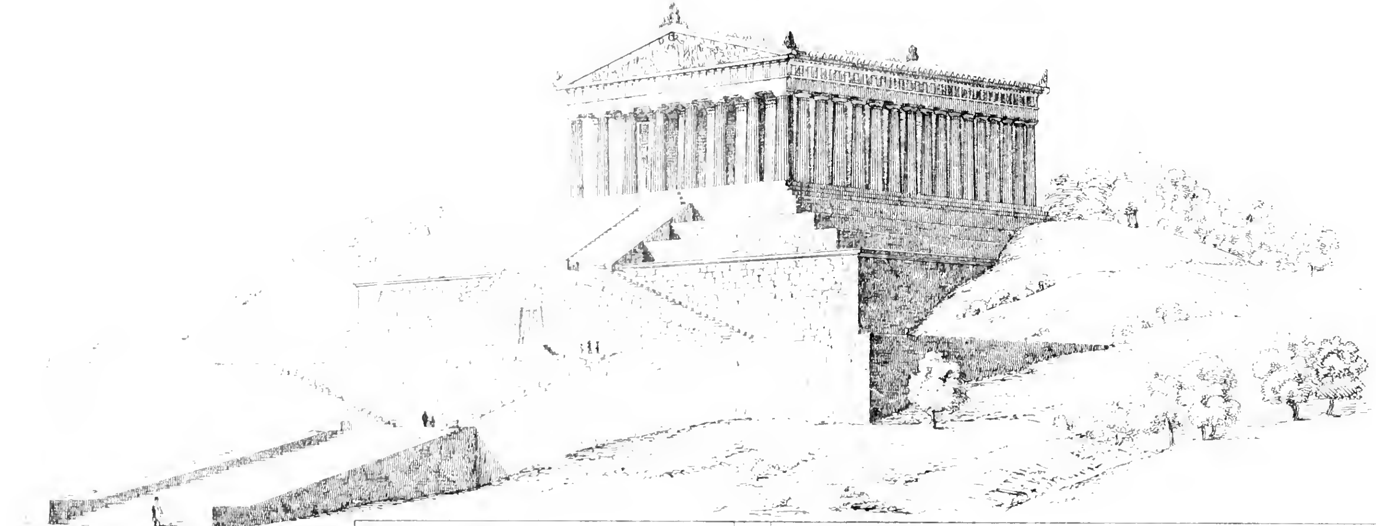
Benjamin Brunton Blackwell, of Newcastle-upon-Tyne, gentleman, and William Norris, of the city of Exeter, civil engineer, for "*an improvement in coating iron nails, screws, nuts, bolts, and other articles made of iron with certain other metals.*"—Feb. 21.

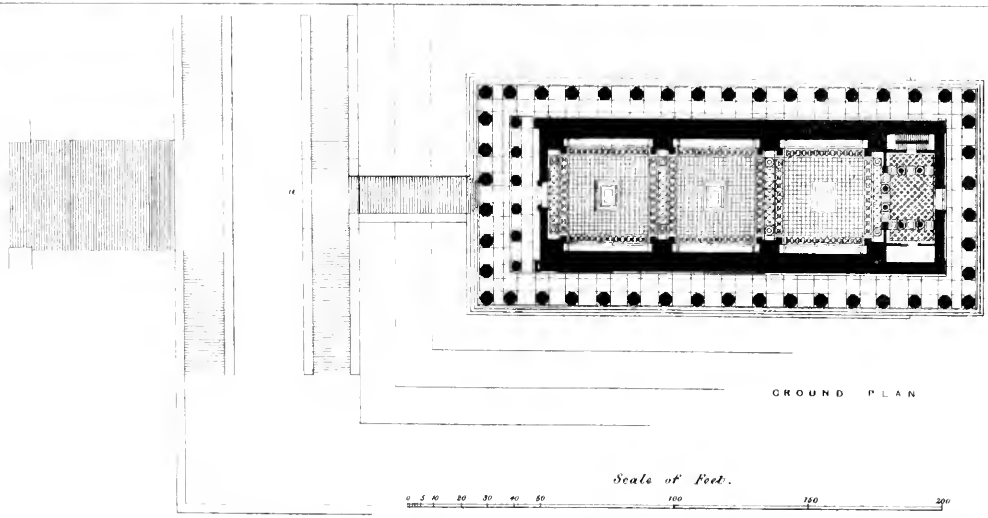
Lawrence Holker Potts, of Greenwich, doctor of medicine, for "*new or improved methods of conveying goods, passengers, or intelligence.*"—Feb. 21.

Henry Clarke, of Drogheda, linen merchant, for "*improvements in machinery for lapping and folding all descriptions of woven textures and surface fabrics.*"—Feb. 23.

Francis Roubiliac Conder, of Highgate, Middlesex, engineer, for "*improvements in the cutting and shaping of wood, and in the machinery for that purpose.*" (A communication.)—Feb. 23.

John Haggerston Leathes, of Norwich, gentleman, and William Kirrage, of the same place, asphalte manufacturer, for "*improvements in coffins.*"—Feb. 25.





The
WALHALLA.

J R Jobbins, 3 Warwick Ct

THE WALHALLA.

Description of the Walhalla, read at the Institute of British Architects,
BY JOHN WOOLLEY, FELLOW.
(With two Engravings, Plates IV and V.[1])

THE idea of raising a monument to the great men of Germany originated with the present king of Bavaria. While he was Crown Prince, and only 20 years of age, he conceived the plan of raising a vast edifice for the reception of busts of illustrious men of every state in Germany, whether Bavarian, Prussian, or Austrian, without distinction, beginning from the earliest records of German history, and including princes, philosophers, warriors, poets, artists, and learned men,—all who might have distinguished themselves by their virtues or their genius. It was in 1804, according to the inscription upon the pavement of the temple, that this noble project was first contemplated by the prince; and though delayed and interrupted at that period, and for some years subsequently, by the disturbed state of his country, his design was never abandoned; but, conceived as it was in youthful ardour, it has been prosecuted with manly energy and constancy, and at length, in the summer of last year, received completion in the magnificent edifice, the Walhalla, which now adorns the banks of the Danube at Ratisbon.

The character given to the building by its mythological appellation, is carried out by the sculpture which adorns the interior, and Klenze has made this "voice of architecture," as Mr. Cockerell terms it, an organ to awaken among artists an interest in a mythology which has been most undeservedly neglected. The adaptation of the national fables of the early Germans to a building so entirely national in its conception as the Walhalla, is most appropriate, and certainly the most original feature of the design. Except merely to state that the name received the consideration of many learned men, the architect has offered no remark upon this employment of the Gothic mythology: probably because the subject is much more familiar to Germans than to Englishmen. For this reason I shall offer no apology for prefacing the description of the Walhalla by a brief account of its mythological prototype, and by a few words upon the northern mythology.

The study of mythology has always held a foremost place in modern education, because the knowledge of the religion professed by the early inhabitants of a country is so essential to the understanding the works of ancient authors, and in order to aid the investigations of the customs and monuments of antiquity. But why the Paganism—called, by way of excellence, classic—should have engrossed so much attention, to the exclusion of a mythology which has so much more claim upon our national sympathy, has been frequently asked, but remains still to be answered. As long ago as the year 1800, the University of Copenhagen considered the matter of sufficient importance to give, as the subject of a prize essay, the question, "Whether the Northern mythology is worthy of equal rank with the Grecian." The question was decided in the affirmative by all the candidates, and Müller, Ohlenschläger, Dalins, and others in their subsequent illustrations of the subject, have fully justified their decision. Without discussing the degree of merit to which each is entitled, it will be readily granted that the Scandinavian mythology, independent of any intrinsic beauty it may possess, has this one great claim upon our attention over the Paganism of Greece and Rome: namely, that we, as well as the other countries of Northern Europe, may esteem these magnificent superstitions as having been the religion of our forefathers; for while the worship prescribed by the Greeks extended itself in Europe no farther than Greece and Italy, the major part of Gaul, Scandinavia, Germany, and Britain, cultivated a mythology and literature peculiarly their own,—a mythology which gives a striking picture of our northern ancestors, and to which our customs, antiquities, and language make perpetual reference.

Upon the conquest of England by the Saxons, the ancient Britons were driven to seek refuge, the principal part of them in that part of France then called Armorica, to which they gave the name of Brittany, and the few that remained in this country in the remote corners of Wales and Cornwall. With their language and their customs the victorious Saxons introduced their fables and their sagas, and the worship of Odin was established throughout the heptarchy.

Hume speaks of the religion of the Saxons as "consisting of superstitions of the grossest and most barbarous kind, as one of which little is known, and which, compared with the systematic and politic institutions of the Druids, made little impression upon its votaries, and which accordingly gave place to the new doctrine" (of Christianity). This is not true; the worship of Odin was one of all others calculated to dazzle and captivate the imagination of a warlike race like the Northmen; and that the laws of that great conqueror took deep root wherever they were propagated,—that is to say, throughout the north,—is beyond all question. Christianity eventually triumphed, not easily, or because it met with no opposition, as Hume supposes; but because truth must prevail over superstition and error. But even Christianity and the lapse of more than eleven centuries have failed to eradicate altogether the traces of this worship: of which fact the names of the days of the week in almost all the languages of Northern Europe is the most familiar instance. The rites of the Druids were the most terrible ever known: their barbarous wicker idol immolations were unknown among the Gothic nations. And another principal feature of their institutions was the profound ignorance which it was the policy of their priests to maintain; for they most carefully concealed their doctrines from the vulgar, forbidding that they should ever be committed to writing: and on this account they had not so much as even an alphabet of their own. The institutions of Odin were entirely the reverse of this. No barbarous people were ever so addicted to writing, as appears from the innumerable quantity of Runic inscriptions scattered all over the north, not excepting England and Scotland. The invention of letters was considered the offspring of Divine intellect, and ascribed to their chief deity; and the characters themselves were supposed to be possessed of magic virtues. The Edda, the Voluspa, and the sagas of this heathen period are still preserved, and are written in a language which is the parent of all the Gothic dialects. The Havamaal, or sublime discourse, ascribed to Odin himself, in which he has delivered admirable precepts to his followers, is the only thing of the kind in existence, and contains profound maxims of wisdom:

> "Which skalds of old have spoken since, in lays of Havamaal
> From race to race descended deep, those sayings fraught with doom,
> And Norway still reveres the same, as voices from the tomb."

The religion of Odin carried with it an innumerable quantity of mythic poems and sagas, and the skalds, or scops, who sung and chronicled these traditions, thus possessed of a mythology so propitious to poetic fiction and ornament, were celebrated throughout the north of Europe: they visited other countries, resided amidst the splendour of courts, and were enriched and caressed by the greatest monarchs of their time. The dawn of northern literature—the only literature which Europe can boast anterior to the adoption of Christianity—is, in short, inseparably connected with the northern superstitions, and the sagas in which they are preserved, must ever remain the earliest monuments of Gothic intellect. So rich a mine has not been neglected by modern writers among the Danes, Swedes, and Germans; many a beautiful creation of genius owes its existence to this source, as the German reader well knows, and the works of Gray, Cottle, Sayers, and especially Herbert, prove that the English are not insensible of the beauties of the northern mythology.* But for the artist, to whom these remarks are addressed, it remains an almost unexplored region of magnificent and poetic fable, which may challenge competition with any which the ingenuity of man has invented. As an instance, it would be impossible to select a more poetical creation of fiction than that of the Walkyriae,—those beautiful, but terrible emissaries of Odin, seen by the dying Scandinavian hero only during his last agonies upon the field of battle, and there upholding his courage

[1] [We are obliged to postpone Plate V, a perspective view of the interior, until next month.—ED.]

* Among these should be mentioned also the translations of Tegner's Frithioff, especially that by Mr. Latham.

to the last, and cheering the dark hour of death by visions of the Walhalla, to which they were come to conduct him.

These beautiful and warlike maidens play an important part in the paradise of heroes, and have been accordingly introduced by Klenze in the building under consideration. Their name, Walkyriae from two Icelandic words, signifies choosers of the slain, as Walhalla means the hall of the slain. Their office was to receive the souls of those warriors who were deemed by Odin worthy of immortal reward, and conduct them to his palace of Walhalla. Led by his beautiful guide, the shade of the hero passes over the bridge of the gods, the rainbow, called Bifrost, which is guarded by the sentinel Heimdal, and they enter the celestial city Asgard, surrounded by ever blooming trees, and full of gold and silver palaces, the mansions of the gods of the Edda. Above this city lies Gladsheim: and here, surrounded by a grove whose trees bear golden leaves and fruit, is situated the promised Walhalla. The hero and his guide approach the western gate, upon which the magic bolt Walgrind, which excludes all unconsecrated souls, falls, and his future residence lies before the hero in all its glittering splendour: gold and silver, brightly polished shields, armour, and weapons, and all the paraphernalia of barbarous warfare, appears on all sides. The Einheriar,—the name given to the future inhabitant of this glorious abode,—upon his entrance, is presented by his guardian Walkyria with his installation cup of mead, Iduna, the goddess of youth, offers him the apples of immortality, and he is at once recognised by his former companions in arms, who have gone to Walhalla before him, with loud shouts of greeting,—"Welcome, Einheriar! enjoy peace and drink mead for ever with the gods!" the future life of these heroes, notwithstanding this reception, is neither an idle or peaceable one. Fighting was an indispensable amusement with our forefathers even in the abodes of bliss. Fighting was their business and pleasure upon earth, and, according to all savage ideas of a future state, they expected to repeat again their earthly pleasures in heaven. Hence arose the custom among the Scandinavians when a chief fell gloriously in battle, to burn with him upon the pyre his armour, sword, and war horse, and whatever else he held most dear. His dependents and friends frequently made it a point of honor to die with their leader, and attend on his shade in the palace of Odin. In the tomb of King Chilperic were found his arms and the bones of the horse on which he supposed he should be presented to the warrior god in Walhalla. A singular instance of this custom has been recently discovered upon opening three tumuli near East Ilsley in Berkshire. In the graves were found skeletons of gigantic persons, together with warlike weapons, rude articles of military equipments, and the bones of animals, probably horses. These persons had evidently fallen in battle, the skulls being fractured, and an iron javelin head being firmly fixed in one of the hip bones.

The pastimes in Walhalla were therefore in accordance with this superstition. In the morning, at the crowing of the golden cock Fialar, the heroes arise with one accord, buckle on their armour and weapons, mount their war steeds, and sally out of the 540 gates of the Walhalla.

> "Fünfhundert Thuren und noch vierzig
> Glanb'ich dass in Walhall sind:—
> Alle Einheriar in Odin's Gehege
> Hanen sich jeden Tag;
> Tod kiesen sie und reiten vom Kampf,
> Trinken Bier mit den Asen und speisen Sahrimner,
> Und sitzen eintrachtig zusammen."
>
> —*Rük's Edda.*

They ride to a mighty plain called Odinstun, and here they fight together with all the fury of their mortal days, performing miracles of bravery until the god Heimdal sounds his horn, upon which their wounds are miraculously healed, and they return amicably to the banquet in Walhalla, the bravest of the day being rewarded with the most distinguished places at the board. Their food consists of swine's flesh, from the hog Sahrimner, which is never consumed, and mead, or hydromel, is supplied by the beautiful Walkyriae, whose duty it is to attend upon them, the gods and Odin himself being present at the banquet.

It should be observed, that warriors of mean birth, and slaves, though dying bravely and in battle, were not admitted to the mansion of Odin; but were received into the palace of Thor, in Bilskirner: noble women were assigned a residence in Folkvang, the palace of the goddess Freia. The unwarlike, and those who had the misfortune to live all the days of their lives,—a calamity which the Scandinavians avoided by voluntarily destroying themselves,—were condemned to an abode in Niflheim, the icy domain of the infernal goddess Hela, from whose name is derived our word hell.

These are the principal features of that portion of the northern mythology which has furnished an appropriate name for a monument to the honor of the illustrious sons of Germany. It might be wished that the architecture of this splendid building had shared in the spirit of nationality of which in all other respects it is so characteristic; or at least that it had been more original in design. But as far as regards the exterior, it can claim the merit only of being an excellent restoration of the Parthenon: the architect has made more than ample atonement for rejecting the mythology of the Greeks by most scrupulously following their architectural model. For this want of invention he seems quite willing to hold himself responsible, by stating that, though the Grecian Doric order was recommended, he was left to the free exercise of his judgment in every other respect. I am, notwithstanding, inclined to suspect that the hint given to the competing architects in the original instructions—to the effect, that an imitation of some approved model of antiquity would be preferred to a less beautiful, though more original invention—influenced him more than he chooses to confess.

The enormous substructure of masonry and large "step-like plinths" upon which the temple is elevated appears to be an injudicious arrangement: it has the effect of making the principal object, the building itself, appear insignificant compared with its subordinate pedestal. The effect must not be judged, however, from a geometrical elevation; for it must be remembered that the building stands upon a considerable eminence, and that the consequent forshortening, when seen from below, must in a great measure obviate this objection.

The arrangement of the interior is very skilful, and in many respects original. The task of introducing a method of roofing unknown to the Greeks, but designed in the spirit of their architecture, was a difficult one, and is well overcome. The roof is of cast iron, of which the construction is visible, leaving open spaces glazed for the admission of light, and by means of sculpture rendered highly ornamental.

The division of the hall by the projecting masses, or wings, which originate in the necessary support of the roof, is a disposition which produces animation and a play of light and shade, and also increases the apparent extent of the building. These wings boldly projecting from the side walls, break the monotony of the simple parallelogram form of the plan, and always conceal a portion of the busts which occupy the lower range of walls, and which, from their great number and similarity, would otherwise have become wearisome. The upper portion of the side walls is visible the entire length, interrupted only by the beautiful Walkyren caryatides which form the principal ornament of the interior, and upon which the eye of the spectator first rests.

The temple, exclusive of the substructure, incloses a space of 234 ft. in length and 107 ft. in breadth, surrounded by 52 Doric columns 31 ft. high and 5 ft. 10 in. diameter. The internal length, including the episthodomus, is 171 ft., the breadth 92 ft., and the greatest height 53 ft. 5 in. Height of the lower order, 28 ft. 5 in.; the upper order, 17 ft. 5 in.; and the caryatides, 10 ft. 5 in.;—height of the temple outside to the summit of the pediment, 61 ft. The substructure is 106 ft. high, 236 ft. in breadth, and 425 ft. in depth. From the level of the Danube to the summit of the temple is 304 ft.

The following description is abridged from the work published by the architect, Leo von Klenze:—

"In February of the year 1814 there appeared in the public papers an invitation to German architects, to prepare designs for the monument which his Royal Highness the Crown Prince of Bavaria proposed erecting to the great men of Germany. The plans produced by this invitation were not satisfactory to his Royal Highness, and I was commissioned to prepare the drawings which have formed the basis of the present design.

"Ratisbon,—a city famous in the history of Germany and Bavaria, and one of the uniting points of the grand roads of Germany, situated upon one of the principal rivers, and in a charming country diversified by valley and mountain, and in a mild climate favourable to building, —Ratisbon was the place chosen by the king as the site of the future Walhalla.

"The 18th October, 1830, the anniversary of that battle which freed Germany from a foreign yoke, was the day appointed for laying the first stone of the edifice. The ceremony was performed by the king in person, and an eloquent oration was pronounced by Edward von Schenck. 'Since civilization and education have been naturalized in Germany,' said he, 'many glorious buildings have been erected; for centuries together has the most persevering art been often employed upon the perfection of a single cathedral. Our country is filled with churches, palaces, fortresses, and castles, and modern times have seen the erection of halls and temples not unworthy of the very father-land of the arts. Statues also, and monuments have been raised to individuals; but since the earliest period of our history Germany has never till now erected an universal monument to her mighty sons. The project of erecting such a monument was reserved for King Louis of Bavaria, and never lived a monarch more worthy to carry such a design into execution.'

"'Let us now,' continued von Schenck, 'look with prophetic eye to the completion of the Walhalla, and contemplate the building as it will one day appear upon the eminence whereon we now stand. What a prospect for the traveller who approaches from the shores of the Danube! Upon the summit of this mountain he will behold a mighty temple of white marble, a hall worthy of the glorified heroes, resting upon mighty Doric columns, embanked by cyclopeian walls and terraces, and approached by extensive flights of stone steps.

"'Having ascended these steps, the sculptured pediment above reminds him of the conquest of the Romans by the Cherusei, and other early battles of the German people. He enters the temple, and his first glance falls upon a sculptured frieze which surrounds the walls, representing the religion, customs, battles, and commerce of the aborigines of Germany. Beneath this frieze, and all around him, he beholds the busts and glorious names of those men who have immortalized our father-land in eveiy braach of art and science, and on every public occasion. The series of these great men commences with those ancient heroes whose primordial efforts broke the mighty power of Rome: to them follows the race of Pepin of Heristhall, the line of noble and mighty emperors of Saxon and Frankish race, the Hohenstaufen, and the race of Habsburger.

"'The line of emperors is closed by those great and good princes who have governed in their own separate countries, or in foreign lands,—such as Otho and Maximillian of Bavaria, Amalia of Hessen, William of Orange, Frederick of Prussia, &c.

"'These monarchs are surrounded by the great men who have been their contemporaries, and who have lived and died for faith and truth, for fame and freedom, or for science and art. Heroes from the Cherusker Hermann, who conquered the Romans, down to Schwartzenberg and Blucher; holy men, like Nicholas von der Flue and Thomas à Kempis; philosophers, as Leibnitz and Haller; Germany's early poets, from the author of the renowned Nibelungen Lied down to Schiller; (long may the bust of Goëthe remain in the Hall of Expectation[2]) the heroes of plastic art, from the old masters down to Mengs; and, last of all, the mighty Dioscuri of German melody, from Gluck to Mozart.'

"[2] Goethe has passed the ordeal which entitles the hero to admission within the halls of Walhalla; his bust will now be found among the best.—T.

"'I can believe,' concluded Von Shenck, 'that the spirits of these great men are now at this auspicious moment hovering around us in gratitude to the noble king who raises this monument to their merits. Their blessing will not be in vain: it is joined to that of Heaven, and descends already upon this building.'

"'While in many other—alas! also German—states, sedition and mistrust threaten to loosen the holy bands between prince and people, here, in Bavaria, stands her king: happy, because he diffuses happiness and prosperity, mighty in the love of his people, justly estimating his high calling, and with conscious power steadily fulfilling it. And thus he lays the foundation stone of a monument to German greatness and German truth.'"

On the conclusion of this oration, the king, standing beneath a baldaquin, supported by columns and surmounted by a statue of Germany, proceeded to lay the first stone of the Walhalla, and the building was commenced in the spring of 1831.

The first large division of the terrace is of Pelasgic construction, and of polygonal blocks of a marble-like limestone; the second division, and likewise the three large step-like landings below the temple, are of the same stone, and formed of regular blocks, but of unequal height and length, as is found in many buildings of the Greeks,—as in the walls of Kalidon, and also in the Theatre of Marcellus in Rome. The columns are 5 ft. 10 in. in diameter, and formed in eleven blocks.

The severe style of the exterior architecture is relieved by the sculpture in the pediments, consisting of highly relieved groups in white marble, by the hand of Schwanthaler, from designs made by the king. The first illustrates the battle in Teutoburger Walde, under the victorious Armenius: the second represents Germany, to whom, after the catastrophe of 1813-14, the representatives of the united forces are presenting the lost provinces.[3]

The site was so chosen that the south end of the temple should present the principal entrance and access for those on foot. In ascending, by means of the different steps and terraces, first to the right and then to the left, the building and prospects of the distant country are presented to the visitor under various and continually changing points of view. Having arrived by 140 steps at the second terrace, a bronze door is seen, which leads to an arched chamber. This chamber is termed the Hall of Expectation, and is intended for the reception of busts of great men still living, from whence, when the occasion arrives, they are removed into the Walhalla itself. Two other flights of steps lead to the pronaos and principal entrance of the temple.

The arrangement of the interior demanded all possible space for the reception of the busts, and their proper distribution was a leading feature of the design. It was necessary that the busts should be all of equal size, and of the Greek therm form; and also, in order to typify the universal equality of all in Elysium, that they should be placed in rows according to their dates only, without individual distinction.

It was then essential that the monotony of the *coup d'œil* of so many similar sized heads should be got rid of. The construction of the roof, which of course could not be left open like the ancient hypethral temples, and which therefore required supporting beams, sustained by four projecting masses from each longitudinal wall so as to lessen their span: this form offered the best means of avoiding the objectionable repetition; and it was thus attained, namely, that in a general view along the hall, a large proportion of the busts would be always concealed from the spectator by the projecting architectural masses. At the extreme end is a large gallery, and in each longitudinal wall a passage introduced, both which during an inauguration or other ceremony, serve for the accommodation of spectators. In designing the building, the architect always had in view the celebration of some solemn and poetic ceremony, as for instance, that certain pe-

[3] Professor Rauch made the original model for this sculpture to a small scale. The execution of it was afterwards entrusted to Schwanthaler, who was then rising into fame. He remodelled the design, and deserves the credit of the entire work, which is of the highest order.

riodical national associations should be held, having for a principal object, the admission of a new bust, and the solemn inauguration of a new hero to the halls of the Walhalla. On such an occasion a processional train would ascend the steps to the first terrace. Here the inaugural bust would be taken from the Hall of Expectation, which would be appropriately decorated for the occasion, and from thence be borne in procession to the next terrace, and so carried into the temple. Upon opening the great bronze doors the procession would be received by a chorus of singers, who would remain unseen in the gallery. Spectators would be permitted only in the gallery and passages, and the hall remain consequently quite free for the train, which would proceed in choragic order to the place appointed for the reception of the bust.

It was important that the interior decoration should tend to promote in the spectator the frame of mind which the foregoing ceremony had awakened, and therefore it was the desire of the accomplished founder of the Walhalla, that the aid of rich descriptive sculpture and ornament should be called in as the most effective means of so doing. In the mythology of our forefathers the Walkyriae were beautiful maidens, whose duty it was to bear dying heroes from the field of battle to the palace of Odin, there to be entertained with never-ending banquets, and to dwell for ever in the paradise of the valiant.

Statues of these beautiful companions of the beatified German heroes, have been employed as caryatides, to avoid the multiplication of severe architectural forms, which are apt to produce mechanical plainness, and also, in order to relieve the monotony produced by so large a number of busts. These Walkyren caryatides, sculptured in marble by L. Schwanthaler, are habited, as near as is known, in the ancient German costume, and are employed to support the cornice and roof. The heroes of the Walhalla are necessarily divided into two classes, namely, those who from the want of existing portraits are recorded only by name, and those of whom busts are really extant. To the first of these is allotted the upper division of the inner compartments of the walls, and their names are inscribed in the spaces between the fourteen caryatides. The busts in a double row, partly upon a continued pedestal, partly upon projecting marble bearers, are divided into six classes, over each of which presides a female therm-shaped statue, sculptured by Rauch, and having reference to the class over which she presides.

In order to complete the allegorical sculpture, the interior pediments formed by the horizontal beams, and the sloping roof, are enriched by three sculptured bas-reliefs, in which are represented the three principal epochs of the northern mythology. In the first is seen the giant Ymer, born of the moisture engendered by the hot wind from Muspelheim and the cold mists from Nifelheim, and from his shoulders spring the first human beings, Askar and Embla. Near him are the Lord of Muspelheim, Surtur the god of light and warmth, and Hela the goddess of Nifelheim. Foliage of the ash and elm [a] fill up the angles of the pediment. In the second pediment appear the principal inhabitants of Asgard; Odin with his spear Gugner, and Frigga with her golden spindle, seated upon their throne Lidskjolf; on the right is Thor with his terrible hammer Miölner, striking the Roman eagle to fragments, and Baldur the youthful god of Eloquence. On the left Braga the god of wisdom and poetry with his goddess Iduna, who, like the Greek Hebe in Olympus, presents the heroes of the Walhalla with the golden apples of immortality. The ravens of Odin fill up the angles. The centre of the third pediment is filled with the mighty ash tree Ydrasil, on the summit of which the eagle of Odin spreads his wings. Beneath the roots flows the fountain of wisdom, with which the tree is watered by the three Nornies. In the angles are the squirrels Rotatoskr.

Beneath this and between the upper and lower orders, is introduced a large bas-relief in eight divisions, which, according to the command of the royal founder of the Walhalla, illustrates the history of the German nation from its earliest period to the introduction of Christianity, and was designed and executed in white marble by Martin von Wagner in Rome. This admirable work, 224 ft. in length and 3 ft. 6 in. high, embraces the following eight principal events. 1st. The peopling of Germany by settlers from the east and the Caucasian countries. A mighty train, in long procession, of wild but beautiful forms, preceded by warriors, followed by their wives and children, and closed by shepherds, are represented passing the river Ister, and engaged in subduing the bear and wild boar, the sole inhabitants of the forests of Germany. In the second division is represented the religion and occupations of our ancestors. In the midst a religious ceremony is being solemnized under a large oak, and horses are being offered in sacrifice. Bards are chaunting the mysteries of the religious rites; and a troop of young warriors is impatiently awaiting the completion of their shields, which an artist is employed in decorating. The third division represents the political and commercial doings of our ancestors; the choice of a leader, the first council of the chosen king with his people, and the intercourse and commerce of the Phœnicians with the northern nations. In the 4th, 5th, and 6th, are represented the contests between the Germans and the Roman empire. In the 7th, the conquest of Rome by Alaric; and the introduction of Christianity by the fervent preaching of the holy Boniface, in the 8th division, concludes the bas-relief.

Respecting the ornament employed, it may be remarked, that without abandoning the long sanctioned Greek contour of form, the architect has employed foliage of German growth, assimilating it as far as possible with the Greek character.

As the adoption of classical architecture was expressly enjoined in the instructions for the edifice, it became necessary to follow what is believed to have been the practice of the Greeks, and unite the charm of colour to that of form. But the architect considers that the striking means which the Greeks employed to distinguish the outlines of their mouldings and members, rendered beautiful and necessary beneath the brilliant skies of Greece, on account of the clearness and light of their atmosphere, is not admissible on external architecture in a northern climate. The interior lithochromic decoration, is as follows: In the ceiling, those parts of the metal construction which are visible, are entirely gilt. The coffers of the ceiling, as well as the soffit of the beams, are coloured azure, and ornamented with stars of white gold or platina, with which, also, all rosettes, screw heads, and fir cones used in the construction are covered. The mouldings of the coffers and panels are likewise gilt and ornamented with coloured foliage. The sculpture and ornamental foliage which fill up the pediment shaped supports of the roof, are pierced and open, and of light form, that they may not appear to overload this essential part of the construction. They are partly of white and gold, and partly coloured after the manner of classic sculpture. The carved members of the cornice of the upper order, which is of white veined marble, is also partly gilt and partly coloured. The frieze is azure, with oak wreaths of bronze gilt. The upper division of the walls is of a reddish brown marble, from the quarries of Oberfranken: the inscription tablets of white marble, the letters of gilt bronze. The Walkyren caryatides of marble of the Danube are entirely but very faintly coloured. The parts representing flesh are ivory colour, the hair fair brown, the bear skin mantle entirely gilt, the upper dress bright violet, the under robe white. The plinth upon which the figures stand is of a warm grey Lumachelli marble; the entire entablature, and the long bas-relief, in the frieze, is of white marble, part from Schlanders, part from Carrara. The carved architrave and cornice are brought out in colour and gold, the relief quite white, and the ground of the ornaments in the frieze azure. The lower division of the principal walls, as well as the pilasters and shafts of the columns, are of brownish red marble from Admet, resembling the antique Africain. The caps and bases of the columns and pilasters are of white marble, ornamented with colour and gold. The carved bearers of the busts, the busts themselves, and the six presiding statues, together with all cantilevers and seats constituting the furniture of the hall, are of white marble without colour or gilding. As the busts could not with propriety have been coloured, it would have been prejudicial to them to have employed gilding or colouring in the sculpture of which th orm a

[a] These were sacred trees.

part. The continued pedestal upon which the first row of busts stands, is of a beautiful yellow marble, from Weltenburg, on the Danube; the plinth is white. The architraves of the doors and windows are of white marble, with ornaments of colour and gold. The doors, plated with bronze externally, are towards the interior, of maple, with studs, and inlaying of bright red amazanth wood.

The floor consists of a variety of marbles, following in pattern the general plan of the interior, and was worked and polished in the manufactory at Tegernsee. In the centre fields are three tablets, upon which, in black letters, upon a white ground, are the following inscriptions: "Projected in January, 1806; commenced October 18th, 1830; finished October 18th, 1842."

Inscriptions on the Tablets.

Herrmann, Conqueror of the Romans	21

List of Busts at present placed in the Walhalla.

A catalogue of the individuals who have, in the first instance, been selected as worthy representatives of the genius of the German nation, will doubtless possess interest for many, nor the less on account of its indicating a very different estimate of worth and celebrity, from what would be looked for by ourselves. While many of the characters that have been selected for such honour, are scarcely known at all in this country, others who are here looked upon as first-rate German celebrities, do not appear. It is true not much more than half the intended number of busts have yet been executed, but those which remain to be added, are exceedingly few in comparison with the host of claimants for distinction. Among artists, Schinkel will almost of certainty be elected; as to Klenze, even when the time shall arrive for his being admitted into the company of illustrious worthies, such compliment may be deemed superfluous in his case, inasmuch as the Walhalla itself constitutes a sufficient monument of his talents and his fame.

	Date of Death.	Sculptor.	Date of Bust.

Goethe, poetry and universal literature	1832	Ditto	1808

A CHAT ABOUT WESTMINSTER ABBEY.

Our metropolitan minster (*west* of St. Paul's), is perhaps without exception, the most beautiful, interesting, and instructive sight in London; and yet how many inhabitants of this great city are there who, but for the accidental visit of a country cousin, which led them to seek the Lions, had never seen it? and how many more to whom it is still unknown ground? They have travelled, perhaps, to York, to see the Minster there; they have sought objects of interest at Cologne; they have thrown their eyes round the Cathedral of Strasburgh—but Westminster Abbey, close at home, has escaped their investigating gaze. Let them lose no time in seeking it out. We feel persuaded that few can visit this wonderful museum of skill, genius, noble thoughts, and memories of good deeds, without an elevation of mind, an improvement in taste, and a chastening in feeling which must tend in a greater or less degree to good. Walk through it, examine it, study it, as often and carefully as you may, you will ever find some fresh claim on your attention, some beauty before overlooked, or some evidence of unpretending piety, which makes you prouder of humanity and more determined to do nothing derogatory in your own person. It is, indeed, a spot "where folly's dancing foam melts if it cross the threshold;" where thoughts that are unholy die; where the past great ones of six centuries speak powerfully to you—it is to be hoped, not uselessly.

The multitude of monuments which it contains, from that of King Henry III, upwards, (omitting, for the present, any remarks on the destructive effect produced by those erected in modern times,) render it an index to English history, and a commentary, while the specimens of the workmanship of different epochs in wood and stone, and glass and metal, which these and other portions of the building present, make it a lecturer on British art and a record of its progress. Edward the Confessor's chapel, at the east end of the choir, is alone a sufficient reward for a pilgrimage of a hundred miles. Here, where old Time seems to have secluded himself from the garish present, and reigns over remnants of the past, are ranged memorials of our early sovereigns—the pious Edward, Queen Eleanor, Edward I, Henry III, Queen Philippa, Richard II and his Queen, and the gallant Henry V. It has nothing in common with the present time, it stands alone, and cannot be realized in the mind of any one of the thronging thousands, who are passing at so short a distance from the spot, if they have not visited it. Examine the pavement, examine the shrines—the chantry of Henry V, the screen, next the choir covered with minutest sculpturing—and see how the powers of art *have* been lavished in honour of God. Our forefathers were not satisfied with the decoration of the mere face of the part in human sight—the highest exercise of their powers was deemed hardly worthy of the temple, and so long as any portion, however remote, or hidden, remained capable of improvement, so long was it deemed incomplete and requiring alteration.

Of the elegance of the Abbey as a structure it is almost needless to speak: it may be termed the finest example of the pointed style of architecture ever executed in England, and remains the most complete, with the exception of the cathedral at Salisbury. The combinations which its various parts form, especially at the eastern end, are as numerous as they are striking, and serve to impress a strong conviction on the mind, of the skill of the old builders, and the power they possessed of so arranging their structures as to excite pleasurable and lofty emotions. Amongst the most striking of these combinations is that presented when standing beneath the porch of Henry VII's chapel, the gloom in which, most artistically devised, serves to render the full flood of light, to be found in the chapel itself, striking and effective in the highest degree. Burke remarks, in his essay on the sublime, "I think that all edifices, calculated to produce an idea of the sublime, ought rather to be dark and gloomy; and this for two reasons; the first is, that darkness itself, on other occasions, is known by experience, to have a greater effect on the passions than light. The second is, that to make an object very striking, we should make it as different as possible from the objects with which we have been immediately conversant; when, therefore, you enter a building, you cannot pass into a greater light than you had in the open air: to go into one some few degrees less luminous, can make only a trifling change; but to make the transition thoroughly striking, you ought to pass from the greatest light to as much darkness as is consistent with the uses of architecture." This the architects of the middle ages well understood; they appreciated the "dim religious light," and accordingly built their ecclesiastical edifices, for the most part, with comparatively few openings. When, however, as in the case before us, the style adopted rendered larger windows necessary, they reversed the arrangement, and so still obtained the required effect. In a Gothic edifice, nothing was done without intention—everything is meaning-full, design is everywhere apparent.

Many of the striking combinations, to which we have referred, are now sadly interfered with by the modern monuments, with which the Abbey is lumbered up—monuments for the most part so absurd that they would make us laugh if they did not make us sad. Mouldings, pillars, and adornments of all descriptions have been ruthlessly cut away for them, openings have been interfered with, and even several of the spaces between the large clustered columns in the side ailes and chapels, are blocked up to the top with tasteless and incongruous masses of stone and marble, alike unsuitable and discordant in colour and design.

The sculpture of the best periods of the middle ages has an entirely distinct and original character, prompted by the spirit of the time and carried out by genius. It is in no way imitated from the master-pieces of Pagan art, which might have been used as models; but is nevertheless full of feeling, and appeals to the sympathies rather than to the eye. In the ancient tombs at Westminster as elsewhere, the sculpture is seen to be a portion of the building, conceived in the same spirit and displaying the same feeling of reverence. All the figures are in repose, all are devotional—there is no flutter, no action even, certainly no worldly action; they do not seek to record, in vain self-glory, any moment of the past, but carry us forward to the great hereafter, and inculcate humility. Alas! how sadly this contrasts with those of more recent date, where every man "for his own hand," has worked in his own way, careless of the general effect, and has not worked well. Mountains of most *material* clouds, urns, flames, figures in ill conceived and violent momentary action, accurate models of periwigs and whiskers, the evanescent fashions of a period of universal bad taste, form the staple—but why endeavour to prove what nearly all seem to acknowledge? A few weeks ago, when the writer said at the Institute of Architects, in reference to the tasteless tombs and monuments with which our cathedrals and churches have been gradually encumbered and overladen, "Like some frightful fungus, they have spread insidiously over all parts of these structures, destroying alike their beauty, propriety, and stability. Our metropolitan Abbey presents a lamentable example of the evil; and it is to be hoped that the acknowledged good taste of those who now govern there, will not merely prevent the increase of this abomination, but lead, as opportunities may from time to time offer themselves, to the removal of the excrescences now deforming that fine building, and to a restoration of its harmonious proportions and original integrity;"—the meeting at once recognized the existence of the evil and reiterated the desire for an alteration. Again we venture to re-urge it. The triforium might be made to contain many of the monuments, as has been done at the Temple Church. Perhaps, too, the Chapter House, which is about to be cleared of its present contents, (dirty shelves and presses,) could receive some without injury to itself, so as gradually to restore to our venerable Abbey its original appearance.

The present state of the ancient monuments is deplorable, and requires immediate attention. Mr. E. Blore, the architect of the Dean and Chapter, when before the Committee of the House of Commons on national monuments, in 1841, said, that he considered these monuments very sacred things, not to be touched without great care and consideration, as more harm than good might be done in attempting to improve their appearance. This is quite true, but there is nevertheless a limit to that forbearance, and this limit has been reached; for unquestionably, unless some steps be taken at once in several cases, nothing will remain to guide the restorer hereafter, and an irretrievable loss will be sustained. We should be right glad to see a general and perfect restoration commenced, a restoration which should include the removal of the ugly western towers put up by Wren, (who knew little of Gothic architecture, and liked it less,) and the completion of the central tower or spire. Some partial repairs and alterations are indeed contemplated, and the plans have been prepared: let us most strenuously urge on the new Dean, Dr. Turton, if it may be done without apparent impertinence, the importance of energy in such a matter as this, and the necessity for the greatest vigilance, in order to prevent not only the occurrence of fresh injuries, but the perpetuation of those already committed.

Amongst the earliest improvements to be made in the Abbey, is the introduction of stained glass in the rose-window and twelve lower openings of the south transept. The execution of this work, after two competitions, was entrusted to Messrs. Ward and Nixon, and is making rapid progress. The subjects for the twelve lower windows are taken from the Old Testament, and may be described as, Noah's sacrifice, Abraham and the angels, Jacob's dream, Joseph interpreting Pharoah's dream, the finding of Moses, Moses before the burning bush, Moses striking the rock, Moses with the tables of the law, David anointed by Samuel, dedication of the temple by Solomon, Elijah's sacrifice, and Josiah renewing the covenant; the figures are the size of life. The large rose-window, besides a variety of symbols, scrolls, sentences, and arms, intended to form a rich piece of mosaic work, conformable to the practice of the old glass painters, will contain thirty-two subjects illustrative of the life of Christ, wherein the height of the figures will be about three feet. The impulse which has lately been given to glass-painting in England is a pleasant sign, and cannot be too strongly aided. So firm was the belief that English artists in this department were inferior to foreigners, that the Chapter, it is said, had nearly determined on sending to Germany for the work in question; luckily, however, one or two members of it were staunch friends to English art, and succeeded in making the present arrangement; the result of which, it is to be hoped, will fully justify them for so doing.

We have not yet looked into the chapel of Henry VII, *orbis miraculum*, as Leland calls it—one of the most beautiful specimens of the last period of Gothic architecture which England or any other country can boast.[1] From its roof, "pendent by subtle magic," to the floor, the whole presents a rich lace-work of decoration. The lover of architecture, after studying the perfect development of the pointed style in the Minster itself,[2] with its acutely pointed arches, its lofty attenuated columns, its infinite divisions, finds here the style which succeeded it when the arch was becoming more horizontal, and when a love of decoration threatened, as indeed did soon afterwards happen, to overwhelm good taste, and lead to the abandonment for a time, of pointed architecture altogether.

With respect to sculpture, Henry VII's chapel presents one of the finest illustrations of early art, in England, in the series of figures which fill the countless recesses in the walls. It is said they were once three thousand in number, but this is perhaps doubtful. They display admirable feeling for art, and will well repay attentive examination. The carving too, in the stalls here, is good, and leads us to express regret that so little encouragement is now given to this branch of art in England. There are a considerable number of artists employed in it at this time, but unfortunately—such is the dominion of fashion, (another word for caprice,)—it is chiefly, if not wholly, in the imitation of old work, to be afterwards stained and sold as such. The upholsterer is the *arbiter elegantiarum*, and the result is, exactly what might be expected under such circumstances. The remedy for this, and many like evils, is, to make artistical knowledge more general, and to induce the multitudes to talk and think on the subject. With an increased public—an extended circle of admirers and employers—the powers of the artist will be more fully called into play, and the more critical that public is, the more strenuous will the efforts of the artist be to maintain himself superior to his judges.

George Godwin.

MESSRS. W. FAIRBAIRN & CO.'S IMPROVED PATENT RIVETING MACHINE.

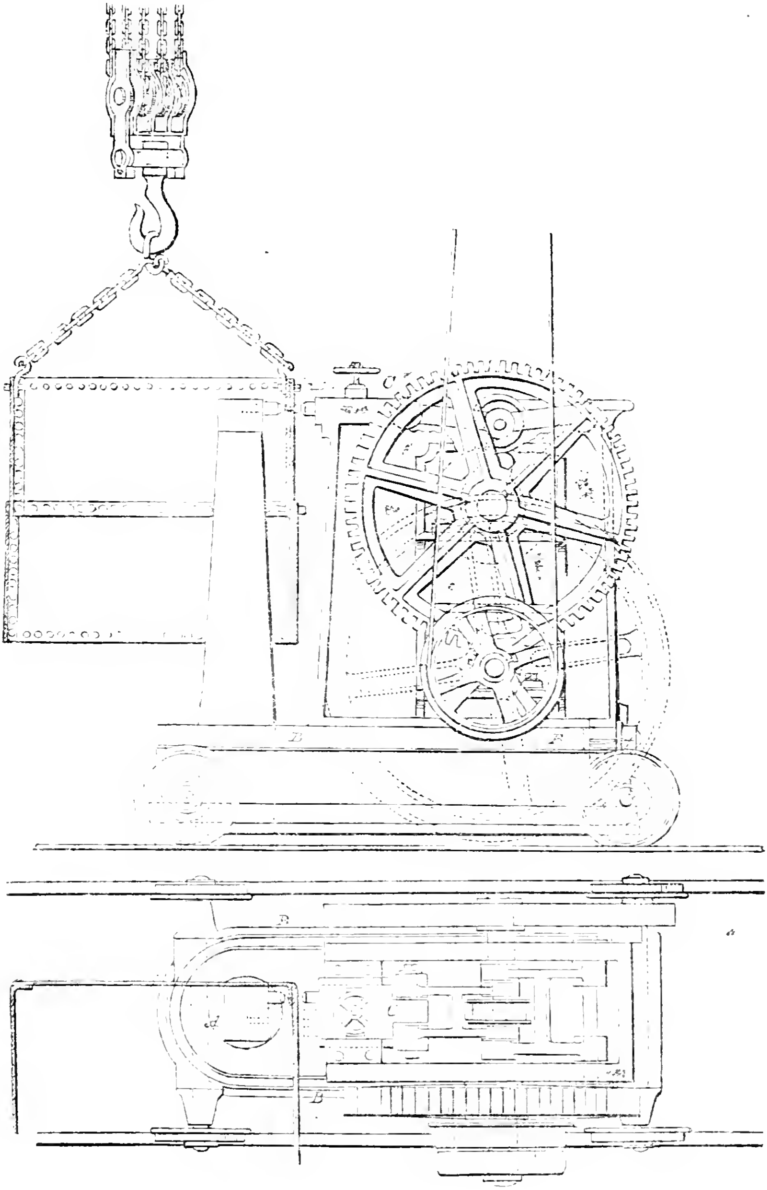
The annexed is a drawing of the Patent Riveting Machine as now constructed by Mr. Fairbairn, of Manchester, drawn to a scale of half an inch to the foot. It is widely different in construction from the machine first made, embodying many improvements, and remedying several defects to which the former was subject.

The machine is worked in the following manner; a strap or band leading from the shafting of a steam engine passes round a pulley, and causes the same to revolve, and with it a pinion fixed upon its axis working into the large spur wheel; upon the axis of the latter is a cam which acts upon the knee joint of the jointed bars at the top, and forces forward the moving slide C, and with it the die against the head of the rivet, and the inner point of the rivet against a corresponding die fixed upon the top of the stem A, the rivet being previously heated in the usual manner.

The large stem A is now made of malleable iron, and having an iron strap B B screwed round the base, it renders the whole perfectly safe in the case of the dies coming in contact with a cold rivet, or any other hard substance, during the process. Its construction also allows the workmen to rivet angle iron along the edges, and to finish the corners of boilers, tanks, and cisterns; and the stem being now made four feet six inches high, it renders the machine more extensive in its application, and allows of its riveting the fire-box of a locomotive boiler, or any other work, within the given depth. In addition to these advantages, it has a broad moving slide C, in which are three dies corresponding with others on the top of the wrought-iron stem. By using the centre die, every description of flat and circular work can be riveted, and by selecting those on the sides it will rivet the corners, and thus complete vessels of almost every shape. Another advantage of this machine is its portable form, and the facility with

[1] Commenced 1503.
[2] Commenced A D. 1220.

FAIRBAIRN'S RIVETING MACHINE.—Elevation and Plan.



which it can be moved on rails, to suit the article suspended from the shears. The introduction of the knee joint is also a very important improvement, as it gives to the dies a variable motion, and causes the greatest force to be exerted at the proper time, viz., at the closing of the joint and the finishing of the head of the rivet.

In other respects the Machine operates as before, effecting by an almost instantaneous pressure what is performed in the ordinary mode by a long series of impacts. The machine fixes in the firmest manner, and completes eight rivets of ¾-inch diameter in a minute, with the attendance of two men and two boys to the plates and rivets; whereas, the average work that can be done by two riveters, with one "holder on," and a boy, is forty ¾-inch rivets per hour; the quantity done in the two cases being in the proportion of 40 to 480, or as 1 to 12, exclusive of the saving of one man's labour.

CANDIDUS'S NOTE-BOOK.

FASCICULUS XLVII.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. "The works of Messrs. Whewell and Willis, honorary members of the Royal Institute of British Architects, reflect the greatest credit upon their penetration and learning:"—so says Professor Donaldson, and therefore so far differs *toto cœlo* from the author of a certain "Encyclopædia," who, although he does not name those gentlemen, gives a pretty broad hint as to the esteem he entertains for them and their works; which last, he has considered unworthy of being named in the list he gives of architectural publications—a list, by the bye, that seems to have been made up from a bookseller's catalogue. However, the "Encyclopædia" has got plenty of puff from some of the country newspapers, therefore, it is to be hoped that Mr. Gwilt will now become quite reconciled to "small-fry critics," of that class, who, if they do not understand anything of the subject, are most conveniently blind to defects and blunders, yet at the same time so lynx-eyed, that they discover wonderful learning and industry, where others detect great carelessness, and the mere handicraft of scissors and paste. As to Mr. Donaldson, his "learned and scientific professional brother," as he styles him, is not likely to be at all pleased at his complimenting the two W's.

II. Donaldson is certainly the most good-natured of critics—liberal of praise even to a fault, for he bestows it so freely as to render it quite common, and hardly worth having; in which respect, however, he does not exactly stand alone, yet one looks for something superior to ordinary puff, from a professional man and a Professor. After that honey, a gentle squeeze of acid from Welby Pugin will prove refreshing; and no doubt he will give us some of it by and bye, in his forthcoming work. His bill of fare promises some relish of the kind; and there are one or two capital tid-bits for him to serve up to us, should he not have overlooked them. It is a pity that he does not mean to give us a chapter on "Lost Opportunities," but a chapter would hardly suffice to enumerate them all—they would require a volume. As to his idea of recommending Gothic architecture, as our general style at the present day, and for public buildings of all kinds, it seems to be somewhat a visionary and Quixotic one. At any rate he will hardly be able to enforce his argument by satisfactory and encouraging examples, proving how successfully we can now accommodate that style to every purpose and every occasion. But what does Pugin himself mean by clapping that odd bristling *chevaux-de-frise* on the ridge of St. George's Catholic church? It looks neither useful nor ornamental—quite the contrary: nor does there seem to be precedent for it, much as it stands in need of authority to reconcile us at all to it.

III. If instead of falling foul on reviewers, anonymous critics, and others of that class, and bestowing upon them a good deal of his "Big bow-wow," as Scott calls it, the illustrious Joseph had condescended to point out some of the best architectural papers that are to be found scattered up and down periodicals, foreign as well as English ones, he would have performed a good office. There are several of the kind in the *Quarterly Review*, although of late that journal has given us nothing on the subject of architecture; and from that entitled the "Modern Palladian Architecture of Italy," he himself might have picked up some information which he does not appear to possess. No doubt there has been a good deal of flimsy nonsense written in periodicals, not only upon architecture, but other subjects also: yet it does not therefore follow that there is nothing at all good, or deserving attention, to be met with in the shape of magazine and review articles; and as the good ones, it seems, bear so small a proportion to the rest, a list of them would not have occupied a great deal of room—though as for the matter of room, Gwilt had more than he knew how to fill up, except by cramming into his book such heterogeneous stuff as tables of compound interest. Taken in general, reviewers—more especially architectural reviewers, may be the ignoramusses Gwilt represents them. Nevertheless, every rule has its exceptions: at any rate, certain it is that some who have written in periodicals are not only professional men, but those who as such stand rather high in public opinion. Professor Pugin, for instance, has written in the *Dublin Review;* and each of the other Professors—Cockerell, Hosking and Donaldson, stands suspected of having occasionally contributed to periodical publications. How they relish Gwilt's remarks may, therefore, easily be conceived. Whether the venerable Vitruvius and the great Palladio were ever guilty of any thing so unprofessional and so horrible, may be questioned, because in their times—oh! happy times for architecture!—there were no periodicals; and if there had been, those great luminaries of art, would not have put their light under a bushel. Surely an "ignorant reviewer" may be excused from admiring Schinkel, when for so doing he had the authority of all Germany. To vent his wroth on such a poor devil, looks like cowardice on the part of Mr. Gwilt, more especially as he might attack architectural heresy in "high places," and display his prowess against giants instead of dwarfs. Besides,

Thyself, friend Joseph, may at times be wrong;
Bethink thee, then. what says the song,
"Remember, where the judgment's weak,
The prejudice is strong."
And there, 'twould seem thy strength most lies.
Reviewers, why should you so rail at and despise?
On them why all thy vengeance wreak—
Reviewers, meekest of the meek,
If not the wisest of the wise?

IV. There is no department of biography in which less has been done than that of architects; and, strange to say, least of all has been done—at any rate in this country—of late years, when even the most eminent—if not exactly the ablest—in the profession have obtained only a mere passing notice in an obituary—hardly so full a one as is bestowed upon some of those "distinguished," persons of whom the world never heard while living, nor will care to remember when dead. Wyatt, Gandon, Soane, Wyatville, Wilkins, and Rickman, have passed away without obtaining more than that kind of notice. In Soane's case, indeed, it was entirely his own fault, for a handsome legacy would have secured him a splendid biographical monument from one who was always telling the world of his esteem for Sir John, but who has since written him plain "Soane," without the knightly prefix, and without *endearing* compliment of any kind. Well, perhaps poor Soane had no relish for "extreme unction," administered by an Egyptian—that is, by a crocodile.

V. "It is found easier," says a writer in the *Edinburgh Review*, "to deal with generalities and abstraction, than to descend to particulars; to frame a theory, or a philosophical essay having the slenderest application to the case in hand, than to direct the criticism to the real appreciation of the work to be reviewed." This is more especially true as regards architectural criticism, or what is given to the world as such: of general remark that has been worn threadbare, there is usually an overdose, while the building which calls it forth, obtains no further notice than two or three lines, and sometimes not even so much. When such is the case, we may without any very great breach of charity, suppose that the writers know not how to apply their own principles—supposing them to be really their own, which is doubtful, and to test by them what they profess to examine and pass sentence upon. Indeed, it occasionally happens that the opinion they express, is altogether at variance with the principles they pretend to lay down:—after twaddling about Grecian architecture, for instance, they will praise what is no better than an abominable caricature or preposterous application of it—at the best a servile copy in regard to mere columns, and those generally introduced so injudiciously as to render all the rest more insignificant in character than it otherwise might have appeared.

VI. Innovation is the bugbear of architects, and is most solemnly of all, deprecated by those who themselves do not possess a fresh idea to start from. Yet what does the history of architecture—or, indeed, of all art, present, but a series and continued course of innovation? How should we have got Gothic at all, without innovation; or having been introduced, how could it have advanced beyond its first stages? Architecture does not indeed admit of fashions, if by fashions are meant fresh patterns every month for dandies of both sexes. But change, growth, and further development, there may and must be; for the very principle of art prevents architecture from continuing stationary. If it cannot advance, it must retrograde, and become entirely mechanical, without aught worthy the name of design. It is owing to our not striving to get forward at all, but confining ourselves to repetitions of the same forms and ideas over and over again, that we at length suddenly abandon them altogether, satiated with the unvarying sameness of a style we have stereotyped, and desparing of obtaining variety, except by going to one entirely different. Thus Elizabethan is taken up by way of change from Grecian, because no one knows how to produce any novelty in Grecian itself.

VII. An architectural book, I am informed, has just appeared, edited by Lady Mary Fox: but "*edited*" has of late become such an equivocal term, that its meaning in this instance is exceedingly doubtful. No one ever heard before that Lady Mary had made architecture her study; and even were she ever so well qualified for the task, it is strange that, merely for the sake of seeing her name so introduced upon a title-page, a lady should condescend to accept the job of superintending the printing of a book. Lady Mary, however, it seems, is not above even crying "stinking fish!" for it is said in the preface that the work, which it seems is partly from the German, is incorrectly translated! If such be the case, it was then surely the duty of her editorial ladyship to revise and correct those portions instead of knowingly sending forth to the public what she was aware was very inadequately executed. At any rate there was no occasion to tell the world how utterly unable she was to get through the *job* she had undertaken, and to confess her own incompetence with a degree of ingenuousness that amounts to stupidity.

OBSERVATIONS ON RIPON CATHEDRAL.

Read at the Royal Institute of British Architects. By Mr. Morris.

> "Edrede with powere amille the north went
> Alle the toun of Ripon he waste and brent."
>
> Peter Langtoft.

In the seventh century an animated controversy divided the polemics of the Anglo-Saxon church concerning the time of celebrating Easter. The Northumbrians observing the Irish tradition, kept the festival upon the Sunday that fell between the 14th and 20th days of the Paschal moon, while in most parts of the country the Roman practice was followed. Thus Bede tells us that two Easters were sometimes observed in one year, and the Northumbrian king and his queen being divided in opinion, it would happen that when the king having completed his Lenten fast was celebrating Easter, the queen still fasting was spending Palm Sunday.

Wilfred, an ecclesiastic, had at the age of 20 been sent to Rome under the auspices of queen Elfleda, for the purpose of acquiring at the papal see, the best information on the subject of dispute, and on his return is said to have taken a distinguished part at the Synod of Whitby, held in 664; and his success was followed by his appointment to the Episcopal Chair of York, from which he was afterwards twice ejected, on the last occasion being absent for 10 years, and it would seem that he visited Rome in both intervals, and found a sure if not a powerful ally in the pope.

In the year 661 Alchfrid, king of Deira, bestowed upon Eata Abbot of Melrose and Lindisfarne certain lands at Ripon, where, allured by the beauty of its situation he built a monastery. But soon after its erection the monks, (among whom was St. Cuthbert,) on account of their nonconformance to the Catholic observance of Easter, were expelled the monastery by Alchfrid, who then conferred it, endowed with 30 hides of land, upon Wilfred, who, notwithstanding his subsequent elevation, retained it during his life. King Athelstan gave it the privilege of sanctuary, which extended a mile round the church, so that not only the church but the whole town was a place of refuge to all who fled to it. One (if not more) of the crosses marking the bounds of sanctuary yet remains.

It would have been strange, indeed, had a prelate, endowed with Wilfred's mental and physical energy, made repeated and protracted sojourns in the "Eternal city," without acquiring some regard for its architectural treasures and a desire to emulate them on his native soil. That he was thus affected, we have the most satisfactory evidence; and ecclesiastical architecture in this country was more indebted to him than to any other person of that age. Notices of his works are found in his biographer Heddins, Richard of Hexham, William of Malmesbury, and other ancient writers, of which a summary sufficient for our present purpose will be found in Britton's York Cathedral and the Chronological Volume. From these we learn that he erected in Ripon a church of hewn stone supported with various columns and porticos, and completed it from its foundation to the summit.

"The church of St. Andrew at Hexham he built, laying the foundations deep in the earth with great care, forming crypts and subterranean oratories, and winding passages. The walls, extending to a great length, and raised to a great height, were divided into three distinct stories, supported by polished columns, some square, and others of various forms. The walls and likewise the capitals of the columns by which they were supported, and the arch of the sanctuary, were decorated with histories and images and different figures, carved in relief on stone, and painted with colours, displaying a pleasing variety and wonderful beauty. The body of the church was likewise surrounded on all sides by *pentices* and porticos, which, with the most wonderful artifice, were divided above and below by walls and winding stairs. Within these winding passages and over them were stairs and galleries of stone, and various methods for ascending and descending, so ingeniously contrived, that a vast multitude of persons might be there and pass round the church without being visible to any one in the nave below. Many oratories also, most retired and beautiful, were, with the utmost care and diligence, erected in the porticos both above and below, and in them were placed *altars* in honour of *the blessed mother of God*, the Virgin Mary, St. Michael the Archangel, St. John the Baptist, and the Holy Apostles, martyrs, confessors, and virgins, with all becoming and proper furniture belonging to them."

I have transcribed this passage relative to the church at Hexham, as its circumstantial character can hardly fail to be interesting; and it illustrates in a very decided manner the highly artificial models copied by the architect. Indeed, I question whether old St. Paul's, Salisbury, Westminster or Durham, in the very zenith of their magnificence, could have furnished more glowing images to the pictoral imagination of the good old chronicler, Richard the Prior, who wrote towards the end of the 12th century, when the church after 500 years, though bowed and stricken with age, retained like a patriarch, the indelible traces of former glory.

Wilfred is said to have erected two other churches at Hexham, besides several in other parts of England; and Bentham supposes that he superintended the erection of the church and monastery of Ely. Indeed, he appears to have been equally celebrated for his theological and architectural acquirements, being eminent for his knowledge and skill in the science of architecture, and was himself the principal director of all those works in concert with the excellent masters whom the hopes of preferment had invited from Rome and other places, to execute the plans which he had formed.

William of Malmesbury also notices the beauty of the pavements; and there is little doubt that where so much emulation existed, an attempt to imitate the mosaics of Rome would be made. In the small, half ruinated, hospital chapel of St. Mary Magdalen at Ripon, is a venerable relic of some such effort, with tesseræ about half an inch square; and on the site of the high altar at Fountains' Abbey, a pavement remains which has glazed tiles of various forms and colours to suit the geometrical figures of the design, which exhibits great elegance and variety; and I think this kind of paving may be considered to have intervened between the former and the inlaid or encaustic tiles met with at Romsey, Salisbury, Winchester, and many other places, an attempt to revive which method has lately been made with some success, and from the present state of the manufactures in pottery, the most beautiful productions may be expected. At Winchester are to be seen some examples of embossed tiles, or with the ornaments raised from the surface or ground.

In Bishop Wilfred's time then we find the church and monastery settled on a permanent footing—his labours and benefactions endeared him to the inhabitants, and the demonstration of rapturous and enthusiastic affection which marked his return from exile, is still commemorated by the annual observance of a mimic pageant. The church, however, that he raised with so much care, and so cunningly adorned, and the monastery whose walls so often reverberated the applause of his virtues, are now no more seen, and the finger of tradition alone, points out the spot where once they stood.

The present cathedral occupies a more elevated and commanding site to the westward. It was commenced by Archbishop Thurston, soon after his advancement to the see of York, (in 1119). The plan was a simple cross, and the style Anglo-Norman with semi-circular and pointed arches promiscuously applied. The walls, as usual in similar buildings, are thick enough to allow galleries or passages to be formed in them. The doors are ornamented with shafts and arch mouldings, in which richness is produced by the repetition of a simple elementary form; and it is worthy of notice, that in the Norman arches the blocks of stone, though moulded or carved in a variety of ways, never wholly lost the original square figure, previously given to them. Without asserting, therefore, that at this period the mouldings and ornaments were actually wrought after the stonework *was set*, such a disposition of the mouldings would tend very much to simplify that process: and it will further be found that these ornaments are not unfrequently modified to suit the actual size of the blocks. There is a low central tower with good detail; and immediately under this is a small crypt or cell, with access from the nave, and also from the choir. To what use it was appropriated does not seem very clearly decided, its extreme dreariness suggesting the idea of a penitentiary; and the small recesses in the sides suitable for the reception of a lamp or crucifix assisting the notion. It may have served simply as a confessional: but whether intended for the momentary reception, or more *perdurable* home of the sinner, or the fugitive from the arms of the temporal power, it is evident that the priest entering from the choir could communicate with and not be seen by a person brought down from the nave. For this purpose there was an orifice in the wall that has acquired the name of St. Wilfred's needle, which the more energetic visitors make a point of endeavouring to get through: and the fine polish acquired by the stone in its contact with silk and broadcloth, show that the attempt is pretty generally made with success. Since the completion of the original structure, no building has perhaps undergone such important alterations without a more complete destruction of its individuality.

The transepts, however, bear more legibly than any other portions, the impress of the 12th century, but the inner roofs appear never to have been completed. Small shafts suited to support the foot of a groin (revealing a purpose unfulfilled) are carried up (here as in many other instances) story after story, and are at last left without adaptation either to a flat or vaulted ceiling; and thus from the absence of an homogeneous and appropriate inner roof half the effect is lost. How lame and abrupt does the flat ceiling at Peterborough appear to an eye that has dwelt on the masculine vaulting of Durham! The cause of the very few instances of Norman groining remaining, except in crypts, and the fair presumption that not many ever existed, is a subject open to investigation, and a speculative idea may be not without its utility in eliciting satisfactory information. Thick as the walls of that period are known to be, the risk that would have attended charging them with stone ceilings, without the auxiliary resistance of external buttresses, may have become an object of anxiety with the builders, and the execution of such works in stone may have been attended with difficulties which even at this time would be considerable, and may then have proved altogether insurmountable, except under the most favourable circumstances, and amplitude of means. The centering alone, if considered for a moment, is an object involving so considerable an amount of expense and practical skill, that we cannot wonder that even in the best days of the art, methods should have been devised for dispensing with it, and hence doubtlessly arose the adoption of wood at Lincoln, York, and elsewhere. Did not the Norman builders feel and shrink from the difficulty like their successors, but without the good fortune to hit upon so happy an expedient? We know that they affected the groin, from its constant adoption in crypts and ailes, when a moderate span facilitated its execution. As the central tower presented the strongest abutments for an arch of any part of the church, it is possible that a groin existed there similar to that at Lindisfarn, in Northumberland, and causes for its non-existence, at the present time, are by no means deficent. Before leaving the transept we may notice that on the east side of each, there is a chapel of two arches; that in the north transept being nearly coeval with the church, and that in the south, of the fourteenth or fifteenth century.

The choir comprised originally three arches only, but was subsequently increased to six. The effect is curious at first, from the circumstance of the triforium arches being filled with tracery and glazed, and the roofs having been lowered. It looks, therefore, like a double clerestory. The addition of the arches appears to have been carefully made to assimilate with the original work, but subsequent alterations bear the characteristic of their own date. In 1319, the church was burnt and greatly injured by the Scots, but restored by the munificence of Edward III, Melton, archbishop of York, and others; and the "steeples" were then added, of which the central one, 40 yards high, was called St. Wilfred's.

There is an old print which shows spires on the central and western towers similar to Litchfield. The former was blown down in 1660, destroying in its fall a part of the south side, of which the reinstatement (said to have been done at the expense of one of the prebendaries) is still perceptible, by the variation in style. After this accident the other spires were removed. In the south aile is a large piscina, probably used for washing the sacerdotal linen, and round the the sides and end there was arched-headed panelling, but part of this is now displaced by the altar screen, erected some few years ago from a design by Mr. Blore, under whom also the groined ceiling was restored, in which are preserved the ancient wooden bosses, which are very beautiful. The east window, erroneously said by Rickman to be of five only, consists of seven lights, and is a fine example of the kind. The clear opening is 48 feet high. Sir William de Plumpton was founder of a chantry at the altar of the Holy Trinity behind the high altar. The act of endowment is dated at Ripon on Wednesday, the feast of the conversion of St. Paul, 20 Edward III, 1345, and was sealed with the seals of Henry de Plumpton, the chaplain first appointed thereto, and of Sir William de Plumpton, which bore the impression of a shield, and on it five fusils, with the name written on the circumference. This chantry was screened from the rest of the church, and under lock and key, but no vestige of it remains.

Near the altar on the south side of the choir are three sedilia and a piscina of curious and elaborate design and skilful execution. The arches are cinquefoiled, the cusps being ornamented with small grotesque heads or other figures, which at the first glance appear to terminate the design; but, on closer inspection, it is found that the small bas-relief first seen is merely the crown of another head in high relief, of a figure falling into bas-relief and covering the soffit of the arch. These figures have human heads with the bodies of quadrupeds. They are of either sex and habited in full monastic costume; and the stout friar is regarding, with an expression too energetic to be perfectly platonic, the beautiful coy, and wimpled [1] nun. Seats of this kind are not of unfrequent occurrence in English cathedral and other churches, as well as in those of the continent: "at Seus, on the epistle or south side of the high altar are five seats. One for the celebrant, (which is highest,) two for deacons, and as many for subdeacons, all officiating while the other priests were in the choir." "*One single seat*," continues the essayist, *(Clark in the Archæologia,)* "is accounted for by the *choir* performing the part of *sub-deacon*, and one priest that of celebrant and deacon. In churches better endowed, beside the celebrant one performed the part of deacon and subdeacon. In such churches were *two seats*. Thus the number was proportionate to the richness of the endowment, and the seats intended for the officiating clergy only. The bishops' seats, were at the east and by the side of the altar. The choir is rich in carved oakwork. The stalls are furnished with misereres and tabernacle work, (which is said to have formed the model for the new work in the choir of York Minster.) The throne is also an object of interest, as presenting one of the earliest evidences of the architectural attainments of the noble Earl, the President of the Institute of British Architects.

The organ screen is of bold and original character, without pretending to the extreme elaboration of that at York. Adjacent to this stands part of a rich stone pulpit. The central tower has for some generations, presented a most singular and heterogeneous spectacle, but at the same time affording to the professional observer a valuable comparative view of the varied proportion and effect of the first and latest eras of true Gothic. In point of expansive lightness, the earlier style is certainly entitled to our admiration, though mass and richness may be exclusively the merit of the latter. Three of the piers of the central tower were cased in the perpendicular period, and the arches of the choir and south transept were also completed; but the fourth pier and the arches of the nave and north transept retain their original form. It is also illustrative of the method pursued to find the perpendicular work carried on the two sides quite up to the battlements. The immense size of the piers and the increased height of the springing, has the effect of contracting the opening of the arch, and also of rendering it necessary to ramp up the longitudinal crown rib of the groin.

Taking our survey in chronological order, the next point for consideration is the west front, which comprises the end wall of the

[1] The wimple is a part of the head dress.

nave and the two flanking towers, each of which is about 28 feet wide and 112 high. The present termination is not original, the battlements and pinnacles being of much later date. As to the mode in which they were originally finished it may be difficult to furnish a satisfactory suggestion: but of that which remains it would be still more difficult to convey an adequate impression. The simplicity of its outline, the unbroken massiveness of its general feature, and the rich and effective detail, respectively contribute to the grandeur of an ensemble unsurpassed by any building of its date.

The lower story has three doors into the church, and the second five successive windows extending the whole width of the nave, with a passage in the thickness of the wall. The second stage has an equal number of windows, the heads of which are elevated towards the centre to compose more readily with the gable, which is filled up by a triple window and trefoil panel. The windows are of two lights with trefoil heads and a trefoil in a circle above. Between the windows are piers of several shafts with foliated capitals, and the pierced pyramid or four-leaved rose; and the wall is very thick here to receive the many shafts and deep receding mouldings with which they are charged. The buttresses of the towers are broad and flat, with shafts in square recesses at the quoins, and run the entire height without diminution; the windows (except that some are filled with louvres) corresponding nearly in form and date with those of the central front. It is an interesting circumstance that the progress of almost every change in this edifice can be traced at this moment with no other guide than a little reflection, and with nearly as much clearness as the most circumstantial chronicle could have recounted them. The Norman nave, for instance, is shown to have extended as far westward as the present, from the fact that the builders in making their addition, left as much of the old work remaining as could be rendered available; and a portion of the old nave has thus been preserved, and the perfect coincidence of the joints of the piers with those of the west wall, show that the formation of the fine arches into the towers from the nave was predetermined in the design of the architect, and not an afterthought as might on a cursory view be imagined; indeed, it may be noticed that the interiors of these towers were finished with great care, and were intended to be entirely open to view from the floor to the roof, where the walls are terminated by a cornice and corbel-table. The moulded piers and arches of the lower stories are very fine, and become plainer in proportion to their remoteness from the eye. At each story was a gallery of communication, not only round the interior of each tower, but across the front from one tower to another.

I should have noticed that while the pyramidal flower is abundantly used in the vertical lines and in the arches, the flattened uncut pyramid, usually called the nail head, is adopted with equal constancy in the horizontal bands and dripstones: yet there is not the slightest taint of monotony discernible throughout. Beautiful as the principle of construction here observed must be generally deemed, giving an appearance of the utmost solidity and strength, with a comparatively small amont of material, it is to be regretted that there was a practical disregard of *bond*, and from the very inconsiderable proportion of horizontal masonry the towers were divided by the windows into four insulated vertical piers, with no adequate tie to meet the contingency of a tendency to spread at the top. The subtle workings of half a dozen centuries, however, manifest the necessity for a precaution that was not contemplated by the builder.

It is, I think, pretty evident that the primary plan was a simple Latin cross, without ailes. The transepts retain their original form, except that chapels have been erected in the east walls, and arches have been opened into the ailes of the nave; while the continuation of the base mouldings, and other external decorations of the towers, attest the absence of ailes at the time of their construction. The present nave may be referred to the close of the 14th century, and is a fine masculine example of that date. It has no triforium, but the clerestory windows are large, and have a gallery running through the piers. The wall ribs which exist indicate the purpose and form of groined inner roofs; bot it is to be regretted that this part of the design has never been effected; and the external pinnacles were also left in an unfinished state.

Although the interior of this church cannot boast much of the rich garniture of ancient monuments or mortuary reliques, its impression and venerable aspect cannot fail to call forth our admiration and respect; and the circumstance of its comprising fine decisive portions of the consecutive styles including Norman and perpendicular, render it an object deserving the careful attention of the architectural student and antiquary.

It only remains to notice a small building on the south of the choir, a lower apartment of which has obtained some celebrity in modern times as the bone-house, from the immense number and symmetrical disposition of the exuviæ of innumerable tenants of yet more circumscribed and darksome chambers, from which they were ejected some half century ago. They are now built in masses like masonry, and exhibit an affecting display, to speak in the language of heraldry of *morts* and *saltires* argent. (There was a similar instance at Sligo and another at Hythe.) This charnel house has certainly the characteristics of extreme age, and the formation of the vaulting accords with the earlier imitations of classic examples. The apsis at the east, and certain external details also, attest its ancient foundation. Immediately above is an apartment now used as the *vestry*, but formerly the chapel, to which the part jost considered formed the crypt. It is entered from the aile of the choir, and is of a very simple character; vaulted, and retains its ancient piscina. This building has been deemed anterior to the body of the Minster: but when we consider the casualties to which, from its position, it would have been subject during the erection of so large a pile immediately contiguous, it will probably be more rational to assign it a contemporary date. May it not have been the lady chapel, or chancel chapel? of which there is a fine example now used as a school at the west end of Norwich Cathedral, with a crypt below; and it may be borne in mind that both Norwich and Ripon are Norman foundations without crypts.

THE EXPLOSIVE FORCE OF GUNPOWDER.

THE recent successful destruction of the Round Down Cliff, at Dover, by gunpowder, of which a full description was given in the February number of our *Journal*, suggests a consideration of the explosive force of that agent, and of the best means of applying its power.

The circumstance which excited most surprise in the blast at Dover, was the absence of all indication of explosive effort. That the cliff should have been rent asunder by the force of the immense quantity of gunpowder employed, was to have been expected; but that the effect should have been produced so gradually, without any report or flame, or other usual accompaniment of an explosion of that agent, appeared contrary to the ordinary conception of blasting operations, and induced the operating engineers to imagine, at first, that the charge had missed fire. The result has shown that Mr. Cubitt adjusted with great exactness, the amount of power to the resistance to be overcome; and it has shown, practically, that the explosive force of gunpowder, in any quantity, may be controlled, and brought to act with a steady effort, like any other moving power. Had the quantity of powder been much greater than it was, or had the same quantity been placed nearer to the face of the cliff, there can be little doubt the blast would have been accompanied by all the usual phenomena of explosion. Had the quantity of powder been less, probably even to a small degree, its force would have been either pent up within the rock, without producing any effect, or it would have found vent by blowing out the tamping.

The force of ignited gunpowder, it is generally admitted, arises from the sudden generation of a quantity of a permanently elastic gaseous fluid, and the expansion of that fluid by the heat excited during the ignition of the powder. The volume of elastic gas generated by the explosion of gunpowder, after it is cooled down to the temperature of the atmosphere, has been determined by experiment to be 244 times greater than the bulk of the powder exploded. It is calculated that the heat produced by the ignition of the powder expands the generated gas into 1000 volumes at the moment of explosion; and that, consequently, fired gunpowder exerts a pressure equal to 1000 atmospheres, or about 6½ tons on the square inch.

The 18,000 lb. of gunpowder used in the blast at the Round Down Cliff would occupy about 300 cubic feet, and the capacity of the three chambers made to contain it was about 750 cubic feet. What space was left between the tamping and the powder chambers, we are not aware; but it would appear, from the published reports of the operation, that the tamping was rammed not far from the powder. We will assume, therefore, the total space within which the gunpowder was confined, to have been 900 cubic feet. This space would be three times the estimated bulk of the powder, exclusive of the containing barrels and bags, therefore its first impulsive effort on being ignited would be $1000 \div 3 = 333\frac{1}{3}$ atmospheres, or about 5000 lb. the square inch; and the force of the permanent generated elastic fluid, when cooled, would be $244 \div 3 = 81\frac{1}{3}$ atmospheres, or about 1200 lb. to the square inch. Now, if we suppose the space within which the gunpowder was confined to have been cubical, each of the six sides would have exposed an internal surface to the action of the gunpowder of 100 square feet, equal to 14,400 square inches. As the pressure, according to the preceding calculation, would in the first instant be equal to 5000 lb. the square inch, the impulsive effort on each side of the cubical chamber would be 72,000,000 lb. or 32,143 tons. As the point of least resistance must necessarily have been towards the face of the cliff, the acting power may be considered as having been exerted only in that direction; therefore the cliff would be forced outwards with an impulse upwards of 32,000 tons. As the rock yielded to this immense power, the pent-up air would expand, and its force would consequently be diminished. The cooling of the generated gas would also greatly weaken its expansive force, and its gradual escape through the fissures of the falling rock would prevent any sudden explosion.

The sound which was heard was that of the rending of the solid rock, and not the firing of the powder; for it is well known that the explosive report of any detonating body is caused by the concussion of the air. This fact is proved by the firing of explosive mixtures of hydrogen and oxygen gases in a strong glass apparatus, for the purpose of obtaining the product of the combustion of the two gases. The apparatus usually employed contains about half a pint, the explosion of which quantity of the mixed gases, when in contact with the atmosphere, is sufficient to produce a report as loud as the firing of a pistol; but when the gases are fixed in a closed vessel, no report whatever is heard. This experiment proves also, on a small scale, the possibility of controlling explosive forces. The expansion of an explosive mixture of hydrogen and oxygen gases at the moment of combustion, amounts to 15 times its original volume, which gives a pressure of 15 atmospheres, or about 225 lb. to the square inch: yet the glass bottle in which the gases are fired is sufficient to control the explosive effort, and to prevent even any sound from being heard.

The quantity of gunpowder requisite in ordinary blasting operations must depend altogether on the hardness of the rock, and the mass intended to be moved. The proper adjustment of the quantity of powder to the resistance to be overcome, forms, however, an important consideration, for an excess of powder is not only a wasteful expenditure of a valuable agent, but it renders the operation more dangerous by the dispersion of fragments in all directions, and it not unfrequently diminishes the effect of a blast by concentrating the direction of the impulsive force. This is particularly the case in warlike operations, where the object in springing a mine is to make the destructive effects extend as far as possible. The aperture produced by the explosion, when a mine is properly charged, is a cone, the diameter of the base of which is double the height, taken from the centre of the mine. This calculation is founded on the supposition that the materials to be removed are either earth or soft clayey soil. The allowance of powder recommended for such mines is about 10 lb. per cubic fathom when the materials are loose earth, and for strong clayey soil about 16 lb. It is found that when the charge of powder greatly exceeds those quantities, the materials immediately above the powder are alone blown up, that the aperture is nearly cylindrical instead of conical, and consequently the sphere of its influence is diminished.

The explosive effects of a charge of powder in blasting, depends also materially on the mode of tamping. This is a point which, until a comparatively late period, was altogether overlooked, and it is not even now so generally attended to as its importance deserves. The notion which formerly obtained was, that the impulsive effort of the powder was greatly increased by ramming it tight. In gunnery practice this is correct; for when the ball is rammed closely to the powder, it is propelled with greater force than when it is not. But the required effects in the operations of blasting are exactly the opposite of those in gunnery. The ball and wadding of the gun may be considered as the tamping of the mine. To blow out this tamping without bursting the gun, is the object in gunnery—to retain the tamping and to burst the chamber holding the gunpowder is the object in blasting. To attain these different ends, the methods adopted in the two cases ought of course to be different. The well known fact that when a ball is rammed only a short way down the barrel of a gun, it will burst before the ball is forced out, affords a very instructive lesson in the practice of blasting, and shows clearly that to produce the most effect in rending the rock, and to run the least risk of blowing out the tamping, ample space should be left between the tamping and the powder. It is true that by leaving such a space for the expansion of the generated elastic fluid, the intensity of its action is diminished, but the same amount of power is distributed over a larger surface; its action accordingly approaches more to that of an ordinary mechanical force, and the liability to split the rock into small fragments is thereby decreased.

One great advantage in mining operations, derived from the practice of leaving a space between the tamping and the powder, arises from its admitting the use of loose dry sand for tamping, instead of requiring the blast hole to be filled and rammed tight with hard substances. The labour, the trouble, and the danger of tamping by the common process, renders the substitution of dry sand a great advantage, as the risk of igniting the powder by striking a spark, is entirely removed; and we suspect that in those cases where it has been found to fail, and the tamping has blown out, that the cause of failure may be attributed to the neglect to leave a sufficient space between the tamping and the powder.

The manner in which the space between the powder and the tamping operates in preventing the latter from being blown out, has been explained in the following manner. The force of fired gunpowder may be considered as proceeding from a point, and radiating in all directions round it. This force must, therefore, participate in the nature of all central forces, and diminish in intensity as the square of the distance. When a ball is rammed close to the powder, it approaches near to the point whence the force emanates, and sustains consequently its full effect; but when the ball is placed farther from the point of radiation, the force acting on it may be diminished many times within the space of half an inch. Suppose, for example, that a musket ball which, when close to the powder, is within a quarter of an inch of the centre of radiating power, were placed a quarter of an inch from contact with the powder, the impulsive force it would receive would be diminished four times. If it were removed to a distance of one inch from the charge, the force acting on it would be diminished sixteen times. If, therefore, we view the first impulsive effort of fired gunpowder as a radiating force, we perceive at once the cause of its diminished action on the tamping of a mine, when a space is left between it and the charge, and whether the tamping materials be sand or hard fragments of rock, the vacant space must be equally advantageous. Should the resistance be too great to yield to the first explosive effort of the gunpowder, the direction of the action of the pent up elastic fluid would cease to be radiating. It would resemble the pressure of compressed fluids, and act uniformly in all directions. The tamping would then be acted on by a power equivalent to the compression of the generated gases, and in a direction tending most effectually to force it out. It is under such circumstances, we conceive, that the tamping, whether of sand or rock, is most frequently blown.

The mode of tamping with dry sand has been brought into notice more particularly within the last two years, in connexion with Mr. Martyn Roberts's plan of blasting by galvanism; but it was known and practised successfully, we believe, 30 years ago, at Lord Elgin's mines at Charlestown, in Scotland. It is to be regretted that an improvement, attended evidently with so many advantages, and which is calculated to prevent accidents in the dangerous occupation of blasting, should have made such slow progress that more than 30 years have elapsed since its introduction without its general adoption.

IMPROVEMENT OF GEODESICAL INSTRUMENTS.

As connected with the profession of a civil engineer, the principles and practice of surveying is an important branch of study; under this term, we do not confine our meaning to the delineation of a few fields, or of a long narrow slip of land, such as railway plans usually present, but to the survey of extensive tracts of country or of islands, usually denominated trigonometrical surveying, because that branch of mathematics known as plain and spherical trigonometry, forms the basis or principle upon which such surveys are carried on. This branch of surveying has hitherto been principally confined to the officers of the corps of royal engineers, by whom the trigonometrical survey of the united kingdoms has been for so many years conducted; but although too much unheeded by students in civil engineering, it forms a legitimate branch of their studies, otherwise they cannot be said to be eligible to occupy such important stations as surveyors-general of our colonial possessions, where such surveys are so much needed, nay almost indispensable. Connected with this subject, the knowledge of the use and adjustments of the higher class of geodesical instruments is necessary, such as theodolites of large dimensions, but more especially an instrument called the altitude and azimuth instrument, from its two-fold application to the measurement of vertical and horizontal or azimuthal angles, and its peculiar applicability to the purposes of so much of astronomy as is requisite in such class of surveying, or we may call it the instrumental link which connects astronomy with geodesy and geography; any improvements, therefore, in the construction of instruments thus connected with the profession we profess to advocate, come fully within the limits of our province, and therefore we are desirous of calling attention to the following extracts from a paper that has been read before the Royal Astronomical Society on January 13th last, entitled "On a new arrangement of a Vertical Collimator attached to the Altitude and Azimuth Instrument." By William Simms, Esq.

"The only essential respect in which the altitude and azimuth instrument now before the society [1] differs from similar instruments by which it has been preceded, is this. The azimuth or vertical axis is perforated and fitted with an achromatic object-glass having a diaphragm in its focus, so as to serve, in conjunction with the spirit-level upon the instrument, as a vertical collimator.

"At present the spider lines in the diaphragm of the collimator form an acute cross, subtending an angle of about 30°; but the preference of this arrangement over two parallel lines placed very nearly together, so as to present a narrow space for bisection, admits perhaps of question; my own habit being that of bisecting an angle by a line, leads me to give to it the preference, although I have found by experiment that very satisfactory results may be obtained by the other arrangement.

"In this state of things, if the telescope be directed vertically downwards, the image of the cross in the collimator will be seen upon the diaphragm of the telescope; and the adjustment, independently of verticality, which must be effected by the spirit levels attached to the instrument, consists in so rectifying the optical axes, that the centres, or intersecting points in the telescope and collimator, remain coincident during an azimuthal revolution.

"The mode of adjustment, described in order, may be as follows, admitting, however, of variation at the pleasure of the observer.

"1. It will be found convenient that the instrument be first generally levelled:—the azimuth axis by turning 180° in azimuth, and correcting by the feet screws of the tripod and the adjusting screws of the spirit levels; but, in all cases, if the error be not beyond the range of the scales, it is far better to leave these screws untouched, and to apply the correction by reference to the divisions upon the scales. The axis of the altitude circle must be rectified by the striding level, exactly in the same manner as in the transit instrument; all which, however, is too well understood to need a particular description, in this place.

"2. To adjust the line of collimation, bring the vernier marked A to 90° or 270° upon the azimuth circle, and, by means of the adjusting screws at the eye end of the telescope, make the middle vertical, or meridian line, bisect the angles of the collimator cross, turn 180° in azimute, and correct half the error by the above-mentioned screws, and the remaining half by moving the object-glass of the collimator.

"3. To correct the nadir point, set the vernier A to 0° or 180° upon the azimuth circle, 90° distant from its former position, and make the middle horizontal line bisect the angles of the collimator cross: turn 180° in azimuth, and correct half the error by giving motion to the telescope by means of the tangent screw, and half by moving the object glass of the collimator. The micrometers should now be set to the zero points upon the altitude circle. By those, however, who prefer numerical corrections to mechanical adjustments, which, when extreme accuracy is aimed at, are always tedious and difficult to execute satisfactorily, the nadir point may be readily determined by reading the altitude micrometers with the circle in the reversed position. The indications of the spirit-level fixed to the micrometer bar must, of course, be carefully attended to in such a determination.

"I shall conclude this notice by observing that the new application of the collimator does not deprive it of any uses and conveniences which it has in any other form, while at the same time it possesses advantages peculiar to itself. Its property, in common with the vertical floating collimator, of enabling the observer to set the axis of the altitude circle perfectly horizontal, irrespective of the riding level, is one which the level collimator does not possess. In common with the others, however, it affords a ready means of verifying and correcting the essential adjustments of the instrument without reference to any external object. An object adapted for such purposes should be both distant and well defined, conditions which imply a clearness of atmosphere perhaps not generally met with in any climate, and much less in that of our own country; moreover the collimator is equally available by night and by day: the light of a small lamp or taper being sufficient to render the lines visible.

"But it has greatly the superiority, particularly in operations out of doors, over the vertical floating, and also over the level collimator, because the latter requires supports independent of, and equally steady with, that upon which the instrument itself is placed; things by no means easy of attainment under any circumstances, and to the scientific traveller often perfectly impracticable.

"Neither is it a small advantage to dispense altogether with an additional instrument, which, to say the least, lessens the number of the traveller's cases, and with them his cares also. An extra instrument may by accident be injured, or through forgetfulness left behind, or for want of time to set up, or a steady support when set up, prove useless when it is most needed. But, by the new arrangement, the collimator becomes part and parcel of the instrument itself, and is so completely protected from injury that an accident could hardly impair or destroy it without at the same time destroying the entire instrument. Its introduction, too, into the perforated axis adds so little to the original cost of an instrument, that it may make a final claim on the score of economy."

[1] An instrument with the collimator attached was exhibited in the meeting room of the society.

THE VELOCITY OF WATER IN VERTICAL PIPES.

We have been favoured with another letter from our able correspondent T. F——n, in reference to our position that water flows down vertical pipes with only half the velocity due to the height when issuing from an orifice. Our correspondent is not convinced by our arguments, and he reiterates his former opinion supported by many illustrations, and by the grave authority of Belidor. The same fault, however, which we before complained of, pervades the whole of his present argument; he takes for granted the question in dispute, and assumes, as established data, the very points respecting which we are at variance. We will let him, however, speak for himself.

"Sir—I am sure that, if all your readers derived as much useful information and pleasing instruction, as I am bound to say I did, from your remarks in the last month's *Journal*, on the 'Velocity of water in vertical pipes,' conveyed in a style at once clear and copious, they must look forward anxiously for the fulfilment of the promise in the concluding passage, of returning at some future period to a subject deserving so much consideration and study. Before you do so, however, I am anxious to point out to you what I conceive to be an error in your reasoning, and, at the same time, uphold the assertions contained in my last letter on the subject.—1st. That the velocity of the column of water in a vertical pipe *maintained full*, is not *half* that due to the height, but that it is expressed by the same formula as for all other falling bodies.—2nd. That cohesion does not satisfactorily explain the continuous flow of water in a vertical pipe; in other words, that there would be a continuous flow in the pipe even if one particle did not cohere to that immediately above it.

"It may appear presumptuous in me to endeavour to reply to your remarks, and to maintain these positions after reading your able article on the subject; but an explanation of them so clear and so obvious has occurred to me; and even your own article contains such ample proof of the truth of my assertions on the main point at issue between us, namely, the velocity of water in a vertical pipe, that even at the risk of being charged with presumption, and under all the disadvantages of endeavouring to maintain a discussion with one superior to me in scientific acquirements, I am tempted to offer you a few more remarks.

"I think it will be well to treat first 'the velocity of the water in the pipe,' that being the chief point of difference, and also because, succeeding in proving this, I think it will appear as a necessary consequence, that the uniform flow of water in the pipe is quite independent of the cohesion existing between 'one particle and that immediately *above* it.'

"You state, and evidently quite correctly, that, supposing a vertical pipe 16 feet in length full of water to have the supporting base removed 'it would be emptied by the fall of water in one second, the final velocity of the water on issuing from the pipe, would be 32 feet per second, and the mean of the initial and final velocities would be 16 feet per second.' This is evidently quite correct. The whole column of water falls like a block of marble; the upper and lower parts are equally subject to the action of gravity, and every particle of water descending equal spaces in equal times, the whole column will fall at once, and this even without supposing that 'each particle coheres to the particle immediately above it,' and quite independently of cohesion, except, of course, what I may term, lateral cohesion, or that existing between the particles of the same horizontal section. The momentum of such a column is, therefore, 16 feet multiplied by the weight of the water; but you also state that, if the pipe had not been permitted to empty itself, but had been maintained constantly full, the velocity of the column of water would be 16 feet, and the momentum consequently the same as in the former case. Would not this conclusion be sufficient to convince you that there is an error in your reasoning?

"In the first case, the momentum, according to your reasoning, is the same as in the second, when the pipe is maintained constantly full. Surely this must be wrong. The mistake appears to me to arise from your not taking into account that, the pipe being supposed constantly full, the water *must enter as fast* as it issues, whether this entering velocity is imparted to the water by the height of the reservoir or other force. If the height of the reservoir or other force, which supplies the pipe with water, is not sufficient to impart to the entering water a velocity equal to that due to the *whole* height of the pipe, then, I maintain that the height of the water in the pipe will diminish proportionally, so as to regulate the issuing velocity according to the supply. I shall endeavour to explain this. No doubt, still supposing the pipe to be constantly full, and, as before, to be 16 feet in length, in the *first* second, the mean velocity will be only 16 feet per second, but for the remainder of the time, the velocity will be 32 feet per second, as will be apparent by carefully considering the following explanation.

"Let us first examine the velocity of the water at different points of the pipe in the first case; when the pipe being supposed full, and the supporting base removed, the water is allowed to fall freely, according to the law of gravitation: that the velocity at any point varies as the square root of its distance from the top of the pipe. At one fourth of the height, the velocity of the water, therefore, will be 16 feet per second; and at a foot from the top the velocity will be four feet per second; therefore, to keep a pipe one foot long constantly full, the water must flow in at the rate of four feet per second; and to maintain one four feet long full, the water must enter at 16 feet per second; if the reservoir does not supply water at this velocity, the pipe will not be perfectly full; and by analogy and following the same train of reasoning, we deduce that the pipe being 16 feet in length, the velocity will be 32 feet per second, and the water must enter the pipe at that rate. Suppose, for instance, the area of the pipe to be one square foot, if the reservoir supplies 32 cubic feet of water per second, then the pipe of 16 feet in length will be maintained constantly full; if the reservoir can only supply 16 cubic feet, then the pipe 16 feet in length will be maintained full only to one fourth of its height or four feet from the bottom; or let us suppose a glass tube 16 feet in length to be maintained full by pouring water from a jug, and let some colouring liquid, of the same specific gravity as water, be placed at the top, it will be found that as the colouring liquid descends, the velocity of the water poured in must be gradually increased until the colouring liquid has reached the bottom of the tube, when the velocity will be found to be 32 feet per second; during this second, therefore, the mean velocity will be 16 feet, and during the remainder of the time the velocity of the water to maintain the tube *full* must be 32 feet per second. If you do not pour in the water at this velocity, you will find, as I before stated that the tube will not be maintained full, but that the surface of the water will fall until the height of the filled part corresponds with the velocity of the supply.

"I trust I have proved even to your satisfaction that my reasoning on this point is correct. I have shown, from your own admission, viz., 'that the final velocity of the issuing water from the pipe in the first class, would be 32 feet per second, and the mean between the final and initial velocities 16 feet per second;' that to maintain a pipe 16 feet in length constantly full, requires the water to enter at the velocity of 32 feet per second, and, *vice versa*, if the pipe be maintained constantly full, that the issuing velocity will be 32 feet per second. The above law is true of any body in vacuo; it is true of shot *in vacuo*; it would be true of shillings, in pleno, falling through a tube without friction, and fitting accurately the sides of the tube, so as to prevent the air from entering at the sides; they would also form a *rope*, and fall uniformly according to the same law, although there is here no *cohesion* in force: it is true from the mere effects of gravitation: but in order to keep up a continuous stream, if I may use the expression, the successive shillings must be dropped from a height such as to impart to them the velocity which the column has already acquired. In this case there is no cohesion, which causes 'one shilling to draw the one immediately above it,' and, therefore, why adduce this property of water to explain a fact when it can be accounted for by gravitation alone which acts on all bodies?

"I have already occupied so much of your valuable space, that I must defer bringing forward many illustrations of the above truths for some future period, hoping that you in the mean time will remember your promise, and enlighten us on a subject at present involved in so much obscurity. Since writing the above, I have met an authority of such eminence and celebrity on subjects of this nature, to support my views, that I cannot forbear quoting him at full length. The authority I allude to is Belidor, in the edition of his 'Architecture Hydraulique,' published at Paris in the year 1737, at page 170, paragraph 429 and 430, it is stated, 'that when a vertical pipe, of which the opening is equal to the base, is allowed to empty itself, the surface of the water acquires in falling a velocity which increases as that of bodies subject to gravity, which fall freely.' This is as you stated. In the next paragraph, 430, he states, 'As it is always possible to render uniform a retarded or accelerated velocity, in taking half of the greatest velocity, this must be done when we wish *to compare the discharge (la dépense) of a pipe, such as the preceding, with one always maintained full*;' and in paragraph 431, always alluding to pipes, 'the velocities of water are in the ratio of the square roots of the heights;' and further on he states that the velocity of the *issuing water* in a pipe *constantly full*, is that due to the *whole* height and not *half*; and also 'we can then, when it is convenient, substitute for the velocity of the water of the column, the square root of the height of the pipe.' I must conclude by requesting any of your readers who are not satisfied with my arguments, to peruse that part of Belidor from which I have quoted the above passages.

"I have the honour to be, Sir,

"Your obedient servant,

"T. F——s."

P.S. "In addition to the extracts which I have already given you from Belidor, I beg to add the following, in order to show more clearly that I have his support to my statement that the velocity is that due to the whole height. Chap. 3, paragraph 438, 'We can then say that the discharge *(la dépense)* of a pipe or reservoir during the time necessary for a body to fall freely from the height of the surface of the water above the bottom, is equal to a column of water which has for its base the orifice, and for height a line equal to the space which a body can move over with an uniform velocity during the time of the fall with the acquired velocity.' Apply this to a pipe of 16 feet; the time is a second, the acquired velocity 32 feet per second, and not 16 feet, as stated in your remarks.[1] Nothing can be more to the point than the above extract. It is true that Belidor has not remarked that the velocity of the whole column, if maintained full, increases every second, although it would appear that he was aware of the fact, from his statement in paragraph 573, when in treating of the momentum of water issuing from an orifice, he states that a pipe can never be maintained full by a reservoir unless the pipe be of such small diameter, that the friction retards the water more than gravity accelerates it.

Placing out of consideration for the present, the minor point respecting the cohesion of fluid particles, we shall confine ourselves

[1] It was the *mean* velocity we stated to be 16 feet per second, and not the final velocity.

strictly to the main question—the velocity of the water—and we shall endeavour to answer our correspondent's objections *seriatim*.

The first objection is founded on the momentum of the issuing fluid. We scarcely know in what manner it is intended to show the fallacy of our arguments, by placing the subject in that light. Our correspondent admits that the mean velocity of a column of water falling through a vertical pipe 16 feet long would be 16 feet per second, and surely if, as we contend, the issuing velocity of water from such a pipe kept constantly full be the same, the momentum in both cases must be equal. We do not see how this consideration proves any inconsistency in our arguments, nor that it gives any countenance to the view taken by our correspondent.

On the next point—the velocity of the water *entering* into the vertical pipe—the whole question may be said to depend. Our correspondent alleges that our "mistake" arises from not considering that the water must enter the pipe as quickly as it issues from it. We maintain, on the other hand, that his error consists in not considering by what force this velocity is imparted to the entering fluid. The water in the reservoir is, by the hypothesis, supposed only just to cover the upper end of the pipe; therefore the action of gravitation on the water between the surface and the top of the pipe can have no perceptible effect. The pipe is also supposed to be constantly full, and the fall of the water down it to be uniform. By what force, then, is the same velocity given to the water in the upper part of the pipe, as to that which has fallen 16 feet? Our correspondent asserts that the velocity of the water at the top of the tube is 32 feet in a second; but we are left completely in the dark as to the nature of the force by which this velocity, which is due only to a fall of 16 feet, can be communicated to the water flowing into the top of the pipe. According to our view of the case, the force which communicates the velocity to the entering water is derived from the action of gravitation on the water falling down the pipe. Part of the force acquired by the water in its fall towards the lower portion of the pipe is communicated to the more slowly moving water above. The tendency to accelerated motion is thus continually checked during the flow of the water by the loss of the motion communicated to the fluid in the upper portion of the pipe, and the accelerated is converted into uniform motion. The laws of dynamics teach, that when accelerated motion is rendered uniform, the resulting velocity is the mean of the initial and final velocities, or one half of the latter; therefore, in a fall of 16 feet, the accelerated motion being rendered uniform, the mean velocity will be 16 feet, which is half the final velocity acquired by a body falling from that height.

In the illustration of the glass tube, when our correspondent says that if the water be not poured in with a velocity of 32 feet in a second, the tube will not be maintained full, he appears to forget that water in pouring only obeys the laws of gravity, and that to pour it into a tube with a velocity of 32 feet in a second, it must fall from a height of 16 feet. In the illustration of the *rope of shillings*, it is plainly admitted, indeed, that in order to obtain a uniform velocity of 32 feet in a second, the shillings must be dropped from a height of 16 feet *before entering the tube*; therefore, even according to our correspondent's own illustration of his case, a fall of 32 feet instead of 16, is requisite to communicate a uniform velocity of 32 feet in a second. We may observe, in passing, that the illustration of the continuous fall of shillings could never be practically exemplified, for we cannot admit that a row of shillings, or of any other non-cohering bodies, would fall in a uniform stream unless they were all allowed to fall at the same instant of time, like a solid bar.

Towards the conclusion of his letter, our correspondent calls Belidor to his aid; and he appears to imagine that thus supported, his position is impregnable. For our own parts we do not see the utility in any course of original inquiry of relying on authorities, however celebrated, as guides where we are professing to take a new road which they have never trodden. If old authorities were permitted to decide new questions, all scientific researches would be limited to the compilation of different and various opinions, and to the decision of their relative values; and we should never advance beyond the present limits of knowledge. The argument of authorities has this further disadvantage, that the opinions quoted very frequently refer to circumstances different from those to which they are applied, and errors thus originating become the more dangerous by the apparent sanction of authorities, which are, if properly understood, opposed to them. The apparent contradictions in the quotations from Belidor, cited by our correspondent, are sufficient to show, either that they refer to different circumstances, or that Belidor had not paid special attention to the velocity of water in vertical pipes, but had, like most other writers, assumed without consideration that the efflux of water from vertical pipes is the same as through orifices. To show the contradictory nature of the opinions to be gathered from Belidor, on the supposition that his words apply throughout to vertical pipes and not to pipes and to orifices alternately, we will quote a passage preceding those referred to by our correspondent. In paragraph 424, he says, when speaking of the cause of the velocity of water flowing through orifices, and contrasting such discharge with the flow of water down vertical pipes, "as the force on the top of the water is absolutely nothing as compared with that at the bottom of an ideal column, corresponding in size with the orifice, it cannot be said that it is this column constantly renewed from the surface which flows out, but that, generally, all the water in the reservoir assists in the discharge through the orifice." He then proceeds to show that if a pipe were inserted in the orifice, and reached to the surface of the water, the exterior of the pipe would bear the pressure of the water in the reservoir, and that the water within the pipe would descend by its own gravity alone, unassisted by the pressure of the other fluid. The circumstances of the discharge in the two cases having been thus distinctly shown by Belidor himself to be so different, he could never mean to assert that the quantities discharged in each case are the same. It must be confessed that he has expressed himself in this part of his work rather vaguely; but M. Navier, who was deputed by the French Academy of Sciences, to superintend the publication of a new edition of Belidor's Architecture Hydraulique, in 1817, adds a note to these passages, from which it clearly appears that he considered Belidor to refer only to the discharge through an orifice, when stating the velocity to be equal to that of a body falling from the height of the fluid.

The authority of Belidor, therefore, would avail our correspondent nothing, even were we disposed to admit that it has any weight in the discussion of a question to be decided by reasoning from facts rather than by opinions. As the flow of water down a vertical pipe is assumed to be uniform, it is evident that there must be some other force than its own gravity which communicates to the water entering at the top of the pipe the same velocity as that which has fallen to the bottom and is flowing out. No attempt is made by our correspondent to show whence this force is derived, though according to his estimate of the uniform velocity, it must be equal to the pressure of another column of water of the same height as the pipe whence it flows. In our view of the case, the velocity of the entering water is derived from the gravitating force of the water descending the pipe; and as the accelerated motion of the falling fluid is thus converted into uniform motion, the velocity can be only the mean of the initial and final velocities of a body falling from the same height.

Iron Dwelling-house.—A large iron mansion has been built by Mr. W. Laycock, of this town, in separate plates. It is to be sent to Africa, where it will be used as a palace by one of the native kings. This singular building has three floors, exclusive of an attic. The basement story is 7 feet high; the second, 10 feet; and the third, in which is the grand suite of state apartments, is 12 feet high. In these his sable majesty will give his state audiences. The principal reception room, the presence chamber, is 50 feet by 30, and ornamented throughout in a style of most gorgeous magnificence. To counteract any annoyance from heat, the inventor has contrived the means of admitting a current of air, which can be regulated at pleasure, to pass through an aperture left between the outer plate and the inner panel.—*Liverpool Albion.*

6. *Floor.*—To sittings, wood; to open spaces, or chancel, stone or encaustic tiles. If not undervaulted, it may be freed from damp by brick rubble, flints, ashes, or furnace slag, laid to the depth of 12 or 18 inches under the floor. Allowance should also be made for the future rise of the surrounding burial ground; the floors of many churches, originally above ground, are at this day many feet below the surface, and have thereby become damp and unwholesome. It is desirable that the church floor should be raised at least three steps above the ground line.

The distance between the joists of the floor should never exceed twelve inches.

All wood floors should be supported on walls, with a clear space of eighteen inches in depth, well ventilated beneath.

No American timber to be used either in the floors or any other part of the building.

Flagged floors should be laid on cross walls eighteen inches high.

7. *Walls.*—To be solidly constructed of stone, either squared, or rubble, or flint: or of brick, where no good stone can be procured without great additional expense. If the walls are of brick, cased with stone or flint, the stone or flint to be well bonded into the brick. As a general rule the thickness must not be *less* than as follows:—

	Square stone of the best quality, or brick.	Brick faced with Flint or Stone.	Inferior stone, Flint, or Rubble.
	ft. in.	ft. in.	ft. in.
If less than 20ft. high, and carrying a roof not exceeding 20ft. span	1 10½	2 0	2 3
If 20 ft. or more high, or carrying a roof exceeding 20 ft. span	2 3	2 5	2 6
If more than 30 ft. high	2 7½	2 9	3 0

The above dimensions are given on the supposition, that there are buttresses, of solidity and form suitable to the style adopted, placed opposite the trusses or principals of the roof; where there are no buttresses, the thickness of the walls must be considerably greater.

No cement or plastering of any kind to be used as a facing of the walls, or of any external part of a church or chapel.

If a wall be built with two faces of stone, filled between with rubble, great care must be taken that they be properly bonded together, as the wall will otherwise not stand a partial settlement. Where good stone is scarce, a thickness, otherwise perhaps unattainable, may be secured by this method of construction.

Walls built of flint or rubble should have bonding courses of stone or brick, and stone or brick piers at intervals, approaching at least within four inches of the external face.

Whatever be the material of which the substance of the walls is made, the dressings should, if possible, be invariably of stone.

The greatest attention should be paid to the quality of the mortar used.

8. *Roof.*—The best external covering is lead, which should be not less than seven pounds to the foot;—or copper of not less than 22 oz. to the foot. Blue tiles, commonly called Newcastle tiles, or stone tiles, are perhaps the next best covering. Westmoreland slates are better in colour than those commonly used, but are, in most cases, expensive. All slates to be fixed with copper nails.

Flat ceilings are inconsistent with Gothic architecture. Next to a stone vaulted roof, none has so good an effect internally as an open roof, exhibiting the timbers. It is desirable that this should be of high pitch, the transverse section forming or approaching to the figure of an equilateral triangle.

If a wooden panelled roof be preferred, the panelling should not be made to imitate stone.

In roofs of low pitch and wide span, horizontal tie-beams are necessary: but in other cases, where the Society is satisfied that due provision has been made for the safety of the construction without them, they may be dispensed with.

If the distance between the principal trusses exceed ten feet, intermediate trusses must be introduced. The distance between the common rafters should never exceed twelve inches.

Wherever the ends of timbers are lodged in the walls, they should rest in cast iron shoes or on stone corbels.

9. *Windows.*—In Gothic churches, where stained glass is not used, the glass should be in small panes, those of a diamond shape being generally preferable.

Hopper casements are recommended, and they should be inserted in almost all the windows, in order to secure due ventilation.

Where lead lights are adopted, copper bands to tie them to the saddle bars are preferable to lead, being less liable to stretch and become loose by the action of the wind.

The very unsightly appearance often occasioned by the wet streaming down the window backs, can be prevented by fixing a small copper gutter at the bottom of each lead-light, to receive the moisture produced by condensation, with copper tubes to convey the same to the outside of the building. This has also a tendency to keep the building dry, and to preserve it from decay; or the inside of the sills may be raised an inch and a half.

A good effect will be produced by keeping the sills of windows raised as much as practicable above the line of the tops of the seats.

10. *Tower and Spire.*—The usual place of the tower, in a church without transepts, is at the west end; or it may be placed about the middle of the side. If funds are scanty, it is better to leave this part of the church to a future period, than to attempt its immediate completion in an inferior manner.

When the tower contains more bells than one, the timbers of the bell framing or floor should not be inserted into the main walls, but should be supported either on set-offs or on corbels.

11. *Gutters.*—Where necessary, to be most carefully constructed to carry off the rain and snow into the perpendicular pipes, which are best of cast iron, cylindrical, and placed an inch or two at least from the wall, so as to admit air and keep it dry.

Dripping eaves projecting very far do not in all cases supersede the necessity of gutters and pipes, even in very sheltered situations; but in exposed places, eaves-gutters, and rain-water pipes will be absolutely necessary to prevent the wet being driven against the walls, and thus rendering the building damp.

Eaves gutters may be made of cast iron; but, unless very skilfully cast, they will not preserve their level.

The lead for gutters must not be less than eight pounds to the foot.

Lead gutters must not be less than twelve inches wide in the narrowest part, with drips at proper intervals; each drip two inches deep at the least, and the fall between the drips not less than one inch and a half in every ten feet.

Outlets to be provided in parapets to carry off the overflowing occasioned by rapid thaws or otherwise.

Drains on the roof should be protected by coverings, as it prevents the melting snow from congealing in the gutter, and thus obstructing the water-course.

Drains should be formed at the feet of all the rain water pipes.

12. *Ventilation.*—Ventilation cannot be always completely effected by windows alone, without incommoding the congregation. In such cases foul air may be expelled at or near the roof, either by horizontal or perpendicular channels or tubes.

Where there is a ceiling, apertures should be made in it for the proper ventilation of the roof.

All the original provisions for the ventilation of the building must be carefully looked after, and the apertures kept open.

13. *Chimneys.*—If any be required, the utmost care must be taken to render them safe from fire. They should never be brought within eighteen inches of any timber. They should be as unobtrusive as possible, but not disguised under the form of any ornamental feature of the building.

14. *The Lord's Table.*—Should be raised two or more steps above the floor of the chancel, which should itself be raised a step or two above the floor of the nave. Where the rails do not extend across the chancel, no seats should be allowed between the rails and the north and south walls; and as much room as possible should be left about the rails for the access of communicants.

15. *Font.*—To be fixed at the west end of the building, or as near as convenient to the principal entrance, but not so as to be under a gallery. Care to be taken that sufficient space is allowed for the sponsors to kneel. The font to be of stone, as directed by the Canon, and large enough to admit of the immersion of infants. To be provided with a water drain.

16. *Reading Pew and Pulpit.*—The reading pew should not be so elevated as to resemble a second pulpit; and both reading pew and pulpit should be so placed as to intercept the view of the east end as little as possible from the body of the church.

17. *Seats.*—The seats must be so placed as that no part of the congregation may turn their backs upon the altar. There must invariably be an open central passage up the whole length of the church, from west to east. No square, or round, or double pews can be allowed, and as few pews as may be. Much accommodation is gained by the adoption, instead of pews, of open seats with backs.

The distance from the back of one seat to that of the next must depend in great measure on the height of the backs and the arrangements for kneeling. Where the funds and space admit, convenience will be consulted by adopting a clear width of 3 feet, or even 3 feet 4 inches; but the width of 2 feet 6 inches in the clear may be allowed if the back of the seat be not more than 2 feet 8 inches in height. This height is in all cases to be preferred, both for convenience and for appearance. If a greater height be adopted, the distance from back to back must not be less than 2 feet 11 inches in the clear. There should not be any projecting capping on the top of the backs. Means for kneeling must in all cases be provided. Hassocks are to be preferred to kneeling boards, especially where the space is narrow.

Twenty inches in length must be allowed for each adult, and fourteen for a child. Seats intended exclusively for children may be twenty-four inches from back to front.

18. *Galleries.*—None can be permitted in any part of the chancel. Where necessary, they should not enclose the columns against which they rest, so as to break the upright lines of the shafts from the floor to the roof. Wherever placed, they should, as much as possible, be made to appear as adjuncts and appendages to the architectural design of the interior, rather than as essential parts or features of it. The Society will not sanction any plan involving the erection of a gallery, unless in cases where it is distinctly shown that no room is unnecessarily sacrificed, by inconvenient arrangements, on the floor.

19. *Vestry.*—The vestry should have access to it from without.

20. *Finishings.*—Wall wainscoting, or wood linings to walls, to be avoided wherever convenient. Wood linings to walls confine the damp, and frequently occasion dry rot. For the same reason cement skirtings are to be preferred to wood, particularly on the ground floor. Where the linings to the walls are of wood, holes should be perforated under the seats to allow the circulation of air. As it is scarcely possible to prevent rot if any wood is in contact with the walls, the ends of seats next the walls should be omitted, and cement, painted, be substituted.

21. *Exciseable and Customable Articles.*—Architects are particularly desired to take care that an accurate account be kept of the quantities of customable and exciseable articles used, where the expense of enlarging or building a church or chapel will amount to £500 or upwards, such as may be duly certified or verified by affidavit.

MR. VIGNOLES' LECTURES ON CIVIL ENGINEERING, AT THE LONDON UNIVERSITY COLLEGE.

SECOND COURSE.—LECTURE XVII, AND LAST; FOR WHICH WE ARE INDEBTED TO THE "MINING JOURNAL."

Before proceeding to a summary of the second course, Mr. Vignoles observed, that there was a material point connected with the subject which had not been sufficiently discussed—viz. the motive power to be employed; on this greatly depended the principles on which a line of railway should be laid out, the end and object being to convey the greatest extent of traffic at the least cost: this cost was compounded—first, of the interest of the capital expended, which should be considered a constant charge; and second, of the periodical working expenses—the work to be done being summed up in the general expression of "overcoming all obstacles to facility of motion." What are these obstacles? They might be divided into two great heads—Gravity and Friction. 1st. Gravity is a natural cause existing under all circumstances, and, affecting lines deviating from the horizontal, in direct proportion to the sine of the angle of inclination. Engineers, therefore, have considered that the first principle in laying out roads, should be (under limits) to approximate as nearly as possible to the horizontal, in order to exclude one of the great causes of obstacle, since, with maximum loads, the retardation arising from gravity is most felt. When such could not be effected, then to distribute the total rise (or effect of gravity) along the easiest ratio of slope. But, in practice, the occurrence of maximum loads, in ordinary passengers and merchandise traffic, forms the exception, instead of constituting the rule, and it is only when a regular and constant heavy trade is to be anticipated that horizontal communications should be insisted on. 2nd. Friction, is a physical cause, varying according to the perfection of the road and of the vehicles moving on it. In the practical working of a railway, however, so many expenses arise under the heads of "conducting traffic, management, &c." common to most lines, whatever the gradient, that they tend to make the cost of overcoming friction and even gravity (particularly with the ordinary light loads) but a small fraction of the total charges. Comparing the amount of obstacles on a railway with that on the ordinary road (where the friction, meaning thereby axletree friction and surface resistance, may be called sixteen to twenty times greater than on a railway), and assuming the inclination on railway and road to be the same, the general result is that the perfection of the railway surface moved over, and the improvement of carriages, or rather that of their wheels and axles, cause the effect of gravity to be felt in the most sensible degree on railways; while the imperfection of the road causes it to be comparatively scarcely appreciated. Hence with the wretched surfaces of the old roads, and the clumsy wheels of our primitive vehicles, the hills seem to have scarcely added to the obstacles to be overcome. As the road surfaces and carriages improved, and increased speed and heavier loads were introduced, the necessity for the greater perfection of the ordinary road became apparent, and the remedy was applied in various degrees during the last 100 years until it was completed as far as possible, in the extensive improvements by Telford and Macneill on our great highways. But in carrying out this principle on railways we have run into the opposite extreme. We should first take in one sum the retarding causes of gravity and friction—viz., the friction, being constant, or nearly so, putting aside the resistance of the air at high velocities, varying only in the perfection of the wheel axles, and in the mode of lubricating, (the surface resistance on railways being, practically speaking, nothing), and the maximum gradient, or rather the gravity due to it:—their sum will be the constant divisor for the motive-power, of whatever description that motive power might be; and, in considering the latter point, it must be the distribution of the traffic, or what may be called the average hourly load throughout the year which is to determine the question. In many instances, in this point of view, it would probably often be found most economical to use animal power, (as is done on the Edinburgh and Dalkeith Railway), were not velocity required—which, on railways, enters so materially into the calculation, that mechanical power in some shape becomes necessary: and this divides itself into stationary power, or when the mechanical means are fixed, and locomotive power, or when the machine travels along with the load. There are two serious difficulties connected with the latter system:—first, a great addition to the load, equivalent on the average to doubling it; and next, that the fulcrum through which the motive power must be transmitted—that is, the rail on which the locomotive driving wheel impinges—is greatly affected by atmospheric causes, occasioning great variation in the adhesion, and consequent uncertainty from slipping of the wheel, so that, as explained in a former lecture, the load after a locomotive engine is really limited by its adhesive power, and not, as might at first be supposed, either by the cylinder power or boiler power. Considered abstractedly, stationary power is cheaper, and always would be so if the traffic were certain and regular, with maximum loads and very moderate speed, even with the present obstacles of ropes, sheaves, and all their contingent complicated apparatus; but at high speed, with a great length of rope, the experience of the working of the Blackwall Railway has shown that for passenger trains only, there was, compared with the most expensively worked lines on the locomotive system, to say the least, no economy in the motive power, though other conveniences arising from the peculiar arrangements on that line, were, perhaps, in this special case, more than an equivalent. A most serious obstacle to stationary power, was the necessity of absolutely stopping, and disengaging and refixing, the trains at each station, which stations could not be conveniently, and certainly not economically, placed further apart than three or five miles, for it could readily be proved, than on a continued distance of six or seven miles of railway worked by a rope, the power of the largest engine that could well be erected, would be absorbed in moving the rope only. The Professor then went largely into a consideration of applying stationary engines as the motive power in working inclined planes under a variety of circumstances, and recommended to the students to consult the valuable work of Mr. Nicholas Wood on this subject, and indeed on all the details of railway working, of which, particularly in the third edition, there was most of the latest information. In many situations, however, where water power could be obtained, the stationary rope and pulley system might be advantageously introduced. Gravity became the motive power, on what were called self-acting inclined planes; that is, when the gravity of a descending train of laden carriages brought up a train of others empty or partially laden: or where skeleton wagons, or water tanks on wheels, could be used as artificial counterbalancing weights in either direction alternately; the circumstances under which self-acting inclined planes could be properly introduced were rare. Mr. Vignoles then gave a clear account of various modes of working self-acting inclined planes; among these was described a curious and interesting one near the great limestone quarries in North Staffordshire; another on the St. Helen's and Runcorn Gap Railway, which he had himself put up, and also the planes for the Great Portage Railway, across the Alleghany Mountains, in the United States of America. Stationary power might also be used to a greater extent on the atmospheric system, whereby, to speak metaphorically, a rope of air was substituted for a rope of hemp or wire, and where no pullies were required, nor any necessary stoppage at the intermediate engines, where only the carriages had to be moved, and where nearly the whole dynamic force generated was made available for motive power. This system had already been explained to the class, and practically illustrated on a railway thus worked, and need not be further alluded to. The Professor was preparing for publication a separate lecture "On the Atmospheric Railway System," to be illustrated with plates and tables, and appendices, in which that interesting subject would be fully gone into, and all the mathematical and philosophical investigations given, with estimates of the cost of such railways under various circumstances of traffic and gradient; fully enabling the value of the principle, as a motive power, to be appreciated. Although modern practice had almost discarded the use of animal power from railways, it might be proper to refer cursorily to it. A horse seems adapted to drag vehicles, from the mode in which he adjusts his muscular action, so as to throw the greatest effect on the line of draft; in making an effort to draw a carriage, the body of the animal is bent forward, throwing upon the latter the part of its weight necessary to overcome the resistance, the muscular force of the legs being employed in keeping up his traction and moving the

TESSELLATED PAVEMENTS,

ANCIENT AND MODERN.

[A work has been recently published, at a great expence, under the direction of Mr. Blashfield, who is connected with the old established firm of Messrs. Wyatt, Parker & Co. the cement manufacturers, for the purpose of exhibiting to the profession what truly beautiful patterns may be adopted in tessellated and mosaic pavements, by the aid of the small porcelain squares recently introduced by Mr. Blashfield for that purpose. The work consists of ten elaborate designs by Mr. Owen Jones, the author of the "Alhambra," splendidly printed in colours. These designs cannot fail in directing the public taste to this admirable description of ornament, for the floors of halls, saloons, conservatories, baths, &c.—we may also add the aisles of churches; for to our taste, it is far preferable to the dingy encaustic tiles. The following essay on the materials and structure of tessellated pavements is by Mr. F. O. Ward who has devoted considerable research in collecting the information.]

The object of the following notice is to call public attention to a new material for tessellated pavements, and to an improved method of constructing the same, by the adoption of which this ancient and esteemed mode of decoration may be re-introduced, at a moderate cost, for the embellishment of our modern buildings. The improvements in question will, it is confidently believed, enable the modern architect to execute mosaic floorings, equal in point of extent and elaborateness to the most celebrated of the remains that have descended to us from antiquity, and very far superior to these in brilliancy and variety of colouring, in the accurate co-adaptation of the pieces, and in the uniform durability of the surface.

In order to arrive at a just conclusion on this subject, it will be necessary in the first place to bestow some attention on the materials and structure of the old Roman tessellated pavements, as described by Vitruvius, and still to be traced in the remains existing in various parts of the country, and in the specimens preserved at the British Museum.

The materials of the best and costliest pavements at Rome (such, for example, as those still remaining in the baths of Caracalla), are coloured marbles of various kinds, differing considerably from each other in hardness and durability. The inferior pavements, found scattered through Britain, France, and other parts of Europe, and along the northern coast of Africa, are usually made of such coloured stones as the neighbourhood happened to supply, with the exception only of the red tesseræ, which are almost invariably of burnt clay. Thus, in the celebrated Roman pavement which was discovered in 1793, at Woodchester, in Gloucestershire, the grey tesseræ are of blue lyas, found in the vale of Gloucester,—the ash-coloured tesseræ of a similar kind of stone, often found in the same masses with the former,—the dark brown of a gritty stone, met with near Bristol, and in the forest of Dean,—the light brown of a hard calcareous stone, occurring at Lypiat (two miles from the site of the pavement)—and the red tesseræ, as usual, of fine brick. These materials differ from each other in point of hardness even more than the coloured marbles of the costlier pavements at Rome; and it is evident that a surface composed of such heterogeneous materials must wear unequally at different parts, and ultimately fall into hollows wherever colours produced by the softer kinds of stone are employed.

If this remark should be met by a reference to remains of ancient pavements, discovered in this country after a lapse of sixteen centuries from their first construction, and still retaining a level unworn surface, it is obvious to reply, that the mere length of their duration gives no force to the objection, seeing that, during by far the greater portion of the time, these pavements have lain buried; and, further, that even when in use they formed floors to the baths and best chambers of the residences of Roman provincial governors, and were therefore, doubtless, subject to very inconsiderable traffic. The entrance hall of a modern club-house would afford a much more trying test of durability; and it will hardly be disputed that a pavement composed of heterogeneous materials would in such a position be liable to wear unequally.

The next point to be observed with reference to the Roman tesseræ, is the want of uniformity in their size and shape, and the consequent irregularity of their junctures, especially in the more minute portions of the design. Whoever will take the trouble to examine the choicest specimens of old pavements at the British Museum (as, for example, one presented by Mr. Lysons, which formed part of the Woodchester pavement referred to above,) will perceive that the tesseræ, instead of coming into contact by smoothly ground and equal sides, are in many places separated by broad uneven lines of cement. In some parts the intervals are of such width that the cement, which in a good pavement should be scarcely seen, forms at least a fourth of the visible surface. It is scarcely necessary to point out the effect which this net-work of brown cement lines, running through the whole design, and mixing a muddy hue with every tint, must have in diminishing the purity of the colours, and in deadening the sharpness and brilliancy of their contrast. It is much as if a picture, when finished, should be crossed and re-crossed all over with lines of brown paint.

Proceeding from these remarks on the materials of the Roman pavements to consider the mode of their construction, we shall find that, while the effect produced was imperfect, the means employed for its production were costly and inadequate to the end proposed.

Vitruvius, in the first chapter of his seventh book on architecture, after describing the manner in which the foundation of the pavement should be formed, goes on to say, that on the topmost layer of cement the tesseræ are to be laid—care being taken to keep the surface flat and true with the level; that, in the next place, all unevennesses and projections are to be worked down by rubbing and polishing; and that, lastly, a layer of cement is to be spread over the whole and scraped off again (in order, it would seem, to fill up any cavities in the cement between the tesseræ, and to render the surface as smooth as possible all over).[1]

We need not dwell at length on the time and trouble that it must have taken to set each tessera separately in the cement, and to try the surface with the level after every few pieces were laid. With respect to the subsequent operation of grinding down and polishing the surface of the work, it must have been in most cases (and particularly where stones of a hard and gritty nature were employed) the most tedious and laborious part of the process. We shall presently see that all these difficulties are obviated by the employment of the newly invented material and mode of construction, which we will next proceed to describe—taking, however, in the first place, a rapid survey of the various experiments which preceded this invention, and of the successive improvements by which it has been gradually brought to perfection.

About forty years ago, a patent was obtained by Mr. C. Wyatt for a mode of imitating tessellated pavements by inlaying stone with coloured cements. Floors thus constructed, however, were found liable to become uneven in use, in consequence of the unequal hardness of the materials; which defect prevented their general adoption. Terra cotta inlaid with coloured cements has also been tried, and found liable to the same objection.

During the last ten years, cements coloured with metallic oxides have been used by Mr. Blashfield to produce imitations of the ancient tessellated pavements; and, for work protected from the weather, the material appears to have answered tolerably well; but for out-door work, required to stand frost, it has been found necessary to employ Roman cement, the dark brown of which gives a dingy hue to all colours mixed with it. This, with some other practical difficulties, has interfered with the success of the plan.

Bitumen coloured with metallic oxydes has also been tried by Mr. Blashfield as a material for ornamental floorings. The groundwork of the pattern was first cast in any given colour, and the interstices were afterwards filled up with bitumen of various other shades. But this method was even less successful than the former; the contraction and expansion of the bitumen soon rendered the surface uneven; the dust, trodden in, obscured the pattern; and the plan, besides being ineffectual, was expensive.

Three years ago, Mr. Blashfield succeeded in constructing an extensive and elaborate inlaid pavement, on the plan of the Venetian Pisé floors. It was made after designs furnished by H. S. Hope, Esq., at whose country-seat Deepdine, in Surrey, it was laid down. It is still in good preservation.[2]

In the same year (1839) Mr. Singer, of Vauxhall, obtained a patent for a mode of forming tesseræ, by cutting, out of thin layers of clay, pieces of the required form, which are afterwards dried and baked in the usual way. His patent also included an improved method of uniting the tesseræ with cement, so as to form slabs of convenient size for paving. He has executed in this manner some very admirable mosaics, and his invention must be regarded as one of the most important steps towards the revival of the art in this country.

We now come to the discovery which led to the invention of the tesseræ particularly referred to throughout this treatise.

In 1840, Mr. Prosser, of Birmingham, discovered that if the material of porcelain (a mixture of flint and fine clay) be reduced to a dry powder, and

[1] This is the general sense of the passage according to the best commentators. The phraseology in the original is here very obscure and has probably suffered from the carelessness of early transcribers.

[2] A floor of a very similar kind was laid down at Mr. Hope's mansion, in Duchess Street, about sixty years since, and it is said to be still in excellent condition.

in that state be subjected to strong pressure between steel dies, the powder is compressed into about a fourth of its bulk; it then undergoes a process of semi-vitrification, and is converted into a compact solid substance, of extraordinary hardness and density; much less porous, and much harder than the common porcelain. uncompressed.

This curious, and as it has since proved, very important discovery, was first applied to the manufacture of buttons, to supersede those of mother-of-pearl, bone, &c. The buttons thus stamped out of porcelain powder are capable of resisting any pressure to which they are subject in use, and are more durable, as well as cheaper, than buttons of the materials ordinarily used.

The applicability of this ingenious process to the manufacture of tesseræ for pavements soon afterwards occurred to Mr. Blashfield; who made arrangements with Messrs. Minton & Co. (the manufacturers appointed to work Mr. Prosser's patent), for a supply of small cubes made according to the new process; these he submitted to various trials and experiments, and having found them in every respect suitable for the purpose, he has recently, in conjunction with Messrs. Wyatt, Parker, & Co., carried out the invention on an extensive scale. Tesseræ of various colours and forms—red, blue, yellow, white, black, brown; quadrilateral, triangular, rhomboidal, hexagonal, &c.—have been manufactured on this principle in large numbers; pavements of considerable extent have already been constructed with them; and they have been found to possess the following advantages:—

First, being formed in similar steel dies, they are of uniform size and shape, so that they can be fitted together accurately in the laying down of the most complicated designs. Secondly, being all composed of the same material, variously coloured, they are all of precisely equal hardness, so that pavements made with them are not liable to fall into hollows in use. Lastly, owing to the effect of the intense pressure under which they are made, they are quite impervious to moisture, of a flinty texture throughout, and, in a word, to all intents and purposes absolutely imperishable.

In these several respects, their superiority to the Roman tesseræ, (which, as we have seen, were shaped imperfectly by hand, and differed from each other in hardness,) must be manifest to the reader. Nor less conspicuous is the superiority of the modern process of uniting the tesseræ to form pavements.

For this purpose (instead of spreading the cement on the surface to be paved, and laboriously setting each single tessera in it, according to the directions of Vitruvius), the pavement is first put together, face downward, on a smooth surface, so that the tesseræ find their level without any trouble to the workman; and as soon as a sufficient portion of the design is finished, it is backed with fine Roman cement, which is worked in to fill the crevices between the tesseræ; the pavement is thus formed into smooth flat slabs of convenient size (according to Mr. Singer's method), and these are laid down on a foundation properly prepared in the usual way.

One peculiar feature of this process is, that private persons, if so inclined, may set out their own pavements in the coloured tesseræ, leaving it for a workman afterwards to cement and lay down the slabs. Fine mosaic work for the tops of tables, for illuminated monuments, &c., may be made in the same manner with a superior kind of tesseræ, glazed on the surface, and richly ornamented in gold and colours.

Pavements thus constructed are singularly beautiful. The outline of the design strikes clearly and sharply upon the eye, and the brilliant colours of the tesseræ are reflected from the level surface, uninterrupted by those broad uneven lines of cement, which in the Roman pavements detract so much from the general effect. The truth of every line and angle in the figure, and the just proportion of all its parts, however complicated and various, impress the mind with an agreeable sense of order and precision. Such, indeed, is the exactness and facility of the workmanship in these pavements, that the oblique and intricate intersections of the Mauresque designs are as readily executed as the simple rectangular patterns of the Pompeiian style. Even the scrolls and twisted guilloches, the quaint emblematical devices, and grotesque representations of horses, warriors, &c., found in the most elaborate of the Roman pavements, may be accurately imitated with the new stamped tesseræ.

The Roman designs, however, have little to recommend them to the modern artist, beyond their historical interest. Even the earliest of them, which are the best, were produced subsequently to the Roman invasion of Greece, when art was everywhere declining; and they abound with indications of the extravagant and licentious taste which grew up amidst the general corruption of Roman manners, occasioned by the rapid influx of foreign wealth and foreign habits of luxurious excess.

When designs after the antique are required, the elements of them should rather be sought in the beautiful decorations of the Etruscan vases, and in the admirable remains of Greek art in general, during its best period—*i. e.* from about 400 to 200 B.C. or during the time of Phidias, Praxiteles, and their immediate successors. (Such are the models which have guided the composition of the magnificent tessellated pavement designed by Mr. Barry, and executed under his direction by Mr. Singer, for the hall of the New Reform Club; a pavement so beautiful and so generally admired, that it can hardly fail to give an impulse to the re-introduction of mosaic decoration, hitherto so sparingly employed by modern architects.)

For Mauresque designs, the mosaic dados of the Alhambra may be advantageously consulted. They are executed in glazed earthen tiles, variously coloured, shaped with considerable exactness, and joined with cement. They present many examples of ingenious arrangement and well-contrasted colouring.

But, whichever of these various styles the architect may adopt, he will find that, for the realisation of his conceptions, there is no material which presents so many advantages as the compressed porcelain tesseræ—whether on account of their uniform size and shape—the purity and brilliancy of their colours—or their extreme hardness, and unalterable durability.

NEW CHURCHES.

At the request of several architects residing in the country, we give the following "*Suggestions and Instructions, as amended May,* 1842," of the "INCORPORATED SOCIETY FOR PROMOTING THE ENLARGEMENT, BUILDING, AND REPAIRING OF CHURCHES AND CHAPELS."

1. *Site.*—Central, with regard to the population to be provided for; dry; if possible, rather elevated, but not on a high or steep hill:—not near nuisances, such as steam-engines, shafts of mines, noisy trades, or offensive manufactories;—accessible by foot and carriage-ways, but not so near to principal thoroughfares, as to subject the service of the church to the danger of being incommoded by noise. The building to stand east and west as nearly as possible.

2. *Style and Form.*—No style seems more generally suitable for an English church than the Gothic of our own country, as developed in its successive periods. The Norman (or Romanesque) style is also suitable, and offers peculiar advantages under certain circumstances, especially when the material is brick. The Society earnestly recommend that, in the proportions and great features, as well as in the details, good ancient examples should be closely followed.

For Gothic churches, the best form is either the cross, consisting of a nave, transepts, and chancel, or the double rectangle, composed of a nave, with or without side aisles, and of a chancel. In a chapel, the single rectangle is also suitable: the length being *at least* twice as great as the breadth. If the funds do not suffice to complete satisfactorily a design, otherwise eligible, or if the circumstances of the neighbourhood render it probable that, at no great distance of time, the building may be enlarged; it is better to leave a part of the original design, as, for example, side aisles or transepts, to a future period, than to attempt the completion of the whole design at once in an inferior manner. In such a case, the temporary walls and fillings up of arches should be so built, as clearly to show that they are temporary, and that the building is incomplete, but at the same time not without due regard to ecclesiastical propriety.

3. *Foundation.*—To be surrounded, if requisite, by good covered drains. If the soil wants firmness, the walls may often be better secured from partial settlements by spreading the footing on each side, than by deepening the foundation, or resorting to more expensive works.

In all irregular or doubtful soils, concrete is recommended for the foundations, in preference to any other material.

No interment should be permitted under a church, except in arched vaults properly constructed at the time of building the church, with entrances from the outside only; nor should any graves be made within 20 feet of the external wall.

4. *Area.*—It would tend much to the preservation of churches, and render them more dry, if a paved opened area, not less than 18 inches wide, were made round them, and sunk 6 or 8 inches below the level of the ground about the church, with a drain from the area to carry off the water. Or the same objects might be attained either by turning a segmental arch from the wall outside the footing, or by bedding in the wall a course of slate in cement.

5. *Basement.*—The inequalities of the ground, the dampness of the soil, &c. often render it desirable to have crypts under a church. They should be of a massive construction, turned upon semicircular or segmental arches, resembling the early examples, entered only from without.

of France and England, especially in the low lands of Lincolnshire and the North, the spire and the tower are found to be the effective and all-sufficient means of obtaining that sublime which man desires in architecture—that conglomerate composition of small stones which a man may carry up a ladder on his back, are in character with the style and the manner of building.

But, recurring to the theory of the art, we find that Vitruvius (lib. i. c. 11.) lays down six principles: order, as addressing the understanding; disposition, as addressing the eye; proportion; symmetry; consistency; and distribution, or economy.

Order, as evincing design, whether geometrical or moral, affects the mind with the sentiment of sublime. Whoever considers the movements of the planets, and understands the laws of their velocities, the curves which they describe, the relations of the periods of their revolutions and their distances, will find himself wrapt in a sublime pleasure, and will recognize a divine beauty of order; but if he turns his contemplation to the fixed stars, in which he can trace no order, and which appear to be disposed fortuitously, the same pleasure is by no means felt.

When a curve is formed by a certain rule and a constant law, as the semicircular vault and the apsis at the end of a church, both which shall be concentric, a great satisfaction is experienced; if these are elliptical, the rule and law is less easily understood; but much more, if eccentric segments are employed, the want of that uniformity is felt, and a kind of violence is done to the eye and understanding. So the rhomboid, and much more the trapezium, displease by their anomalous and unequal angles. No predetermined counsel, order, or industry are evinced, and the essential sense of order is dissatisfied.

If the philosopher finds any natural production—a stone, or a root—assuming the regularity of a geometrical form, he judges it worthy of a place in his museum: such is the love of order. Individuals in a mob have neither force nor effect, but ranged in regimental order they acquire a new quality. So trees planted in avenue have, in many situations, an effect superior to the forest. The desire of imparting variety to his work, often misleads the architect from this important principle of his art; forgetting that his building is to derive its chief effect from the contrast of its regularity and order with the surrounding irregular objects and scenery, he seeks, too often, to make his own building his picture, and to engraft upon it that variety which the scenery ought to supply. Thence picturesque architecture, which has diverted the student from the ancient principles, universal amongst the old masters. Succession and repetition of impression by parity of objects, by regularity and order, the isometrical colonnade or Gothic arches of the nave, or equidistant windows along an unbroken front, have more energy and effect than all the varieties of such features that can be contrived. The surrounding irregularities make order tell by their contrast.

Vanbrugh was remarkable for this quality, and he knew at the same time how, by the composition of his parts, to produce, from certain points of view, the utmost variety of combination and picturesqueness, while, from others, the whole was perfectly regular.

Perrault observed order rigidly, as did Wren; while by the contemporary fashionable architects amongst the Italians it was totally abandoned, as may be remarked in the front of St. Peter's, and in the works of Bernini, Borromini, and Maderno. Columns in groups, or at irregular distances, broken entablatures, for the sake of a repetition of profiles, curvilinear fronts, and such scenery as belongs to painting, established the novelty of picturesque architecture—a solecism in art, and a contradiction in terms, unless by combinations from certain points of view as above.

If we call to mind the fact, that the greatest architectural efforts have usually followed periods of political and moral disorder, we may recognize in such works that natural love of order, which revolutions and tumults have denied. Certain it is, that after a long period of civil tranquility, architectural efforts, especially of regular order, have ceased to be fashionable, and the picturesque or the irregular is resorted to as a change.

Disposition or composition of the various features of an architectural work, is the second principle laid down by Vitruvius. It consists, says he, of the idea of the ichnography; the idea of the orthography, or elevation; and the idea of the scenography, or view in perspective, taken on the angle. "These," continues he, "are the result of thought and invention; thought, full of attention, application, and vigilance, accompanied with *delight*; and invention, which is a solution of different problems by new applications seized with *promptitude*."

Thus he proceeds as nature does: putting the purpose or the plan *first*, to which the figure of the object adapts itself *secondly*, and thus each composition displays peculiar features; and the appearance of his buildings would be as various as their purposes; whereas modern architects often reverse the method, and they constrain the plan to a preconceived orthography. How otherwise is it that we recognize the master the moment we see his work? The orthography ever the same, and the plan adapting itself as it can: so we commonly put the cart before the horse.

But the exact conception of the ultimate effect of the building, the realization of the prophetic vision of the architect, are of extreme difficulty, and subject to lamentable disappointment. They can be attained only by great knowledge of perspective, and by careful models; and the greatest masters have been most remarkable for their reliance on such means.

"The architect," says Wren, "ought, above all things, to be well skilled in perspective, for everything that appears well in orthography may not be good in the model, especially when there are many angles and projectures; and everything that is good in model may not be so when built, because a model is seen from other stations and distances than the eye sees the building. But this will hold universally true, that whatsoever is good in perspective, and will hold so in all the principal views, whether direct or oblique, will be as good in great; if this only caution be observed, that regard be had to *the distance of the eye in the principal stations*."

In this last particular the methods of the different masters have varied materially. For instance, Vanbrugh always supposed himself at a distance of 500 to 1000 feet from his buildings; consequently his sky line and contour are well studied, but his details wholly neglected, and the pleasing effect of his buildings in approaching them; whereas Adams supposed himself from 50 to 100 feet only from his buildings; consequently they have no contour from a distance, but are full of elaborate detail on the approach.

The visual angle, extending at most to 45°, should be carefully applied to the points of distance; and the scale of the drawing or study should be correctly adjusted to this distance, so that no misconception should arise. A study for a building to be seen at 100 feet distance only, will be on a large scale, and occupy the whole height of the paper; whereas, seen at 500 feet, it may be only one-fourth that size.

The Greeks were consummate masters of this branch of optics, as we should doubtless have known had Aristotle's work on taste been preserved to us. The terms synoptic and eusynoptic correspond with the points of view which all their arrangements were calculated to afford.

The Parthenon and the Temple of Jupiter Olympius—indeed, almost all the great temples—were approached on the angle, the periboius and the propylea by which they were inclosed, concealing great part of them, until they could be contemplated to the utmost advantage from a synoptical point of view. The plans of Palmyra and Balbec, and those of Rome, preserved to us by Palladio, are lessons, in these respects, demanding the most careful attention.

It is obvious that street architecture, being seen chiefly in flank, should be treated otherwise than buildings at right angles with the point of view, as triumphal arches, or terminations to the vista.

In the 15th and 16th centuries perspective delineation became a new art in the hands of Lombardi, Bramante, Peruzzi, Raphael, and lastly the renowned Pozzi; and though Vitruvius assures us that in the 5th century B.C. Agatharcus wrote a treatise upon perspective, it is probable that the ancients never arrived at the skill attained by those masters.

But perspective calculation applied to architecture, and the adjustment to the point of view, was undoubtedly better understood practically by the ancients than ourselves, as their remains abundantly prove. The vista which shortens the length and discloses the end at once—the exposure of the entire object staring from a distance as well as near—the placing colossal objects in colossal places, are all modern mistakes. The temple at Luxor, the colonnade at Palmyra, are deflected in angles, so that the bounds are concealed, the successive columns disclose themselves by degrees, and the length seems interminable. The temple is partially hidden, and excites the imagination from the promise of its roof, entablature, and capitals, until it is permitted to be seen in its overwhelming majesty.

The columns of Trajan and Antonine are placed in confined positions, and the effect is tenfold.

Palladio was remarkable for the adjustment of his building to the position, of which the Town Hall at Vicenza is one of the most remarkable examples; and the surprise and admiration of the traveller who has known that building only in the orthographic engravings can never be forgotten.

Vignola is said to have made his studies of his buildings at the points of view from which only they could be seen.

It is quite certain that Sir W. Chambers was less master of this part of his art than of many others. Any one visiting the front of Somerset House, in the Strand, is satisfied with its scale and sufficiency in all respects; but when he enters the spacious quadrangle, and looks on the back of the same building, he experiences some disappointment; he finds the scale too small for the size of the quadrangle; but much more, when he observes the same proportions from the opposite side of the river, he deplores their littleness and want of mass and feature, the petty dome in the centre, and the confusion of chimney shafts which disfigure the roof. Had Vanbrugh disposed the river front, we should have seen those chimney shafts united in towers; the whole outline or sky-line would have been marked and varied with emphatic features, suited to the scale of the river and the majestic position given to the building.

"It is the part of a wise man," says Alberti, "to have the idea of his work well fixed in his imagination. The ancients, therefore, not only by perspectives, but by models of the whole, and of parts, submitted their works to practised men before they laid a stone. Such models should not, however, be pretty toys, in which delicacy of workmanship draws the attention from the merit of the design. Finally," continues Alberti, "when the model satisfies the architects and practised judges, I recommend that there should be no hurry to begin, but if possible time should be allowed that the conceit of the design may cool; when, having laid aside the natural overweening affection for your own production, you may judge more justly of its effect. Time discloses many counsels for the advantage of our undertakings; and many defects, which at first escaped attention, at length become apparent." Scamozzi used to say, that pretty little models were like pretty little birds, no one could tell whether they were masculine or feminine; but if made large, you might then discern which was an eagle and which a crow.

Vitruvius, lib. vi. c. 11, and lib. iii. c. 111, refers to optical effects.

Proportion is the third principle set forth by Vitruvius, the most difficult and the most precious to the architect, and no less a golden rule in his art than in that of the arithmetician. Symmetry, which is the fourth principle of our author, is, by a vulgarism, often mistaken for proportion; but the etymology defines its meaning, as correspondence or parity of parts on either side a centre; at most it may signify proportion of aliquot parts. No part of architecture has occupied the speculations of the ingenious more than proportion, and those who have not found the analogy of the human form, as set forth by Vitruvius from the Greeks, sufficient, have endeavoured to find a more certain analogy in the laws of musical sounds: Blondel, Ouvrard and others, may be consulted on this point.

To the artist observer of the proportions and forms of animal nature, the Greek analogy seems to develop the science of proportion in the comparison of animals of the same genus, but of various species, sufficiently to show that beauty resides in inequalities; the measure of those inequalities is, indeed, not so easily defined; but the establishment of the fact may help the architect to some valuable conclusions.

Thus, if we divide the human profile, the forehead, the nose, the upper lip, and the chin, into equal parts, we have ugliness: the profile of the Apollo presents these parts in *inequalities*, and upon the nice variety of these beauty depends.

The satyrus, or baboon, is ugly, compared with the man: amongst many other reasons, for this, especially to the architect, that his proportions approach equalities. The baboon is six heads high: his arms equal the entire length of his body and legs; the subdivisions of the arm, the hand, the fore-arm, and os humeri, are nearly equal; so also the foot, the leg, and the thigh. If these proportions are compared with the human form divine, in which they are all in different and unequal lengths, the cause of beauty will be at once apparent. The human figure is eight heads high, and is inscribed by Vitruvius in a square, whereas the baboon is inscribed in a figure of less beauty, namely, a parallelogram of six by eleven, such is the length of his arms. Thus, again, if we inquire why the ass is so inferior to the horse, we shall find the same answers. The one is little more than two heads to the shoulder, while the horse is 2½; the ears of the ass approach equality with the head or neck. The scapula to the os humeri, in the ass, four to five, in the horse is four to six; the metacarpus to the radius three to five in the ass, is 2½ to five in the horse.

The Professor exhibited drawings in illustration of these remarks, and stated, that the same relations applied to vegetable nature, and that beauty there, also, would be found to reside in inequalities; and he proceeded to show, that orthographic equalities in the vertical features of architecture, both in the divisions of floors and orders, and in details, were always evidences of the decline of taste. In Greek profile it would be found universally, that the inequalities constituted their charm; in the Roman they were not so nicely observed; in the Byzantine, the plain and moulded surfaces approached equalities. So in Gothic architecture, the period of the thirteenth was far superior to any other in this respect; of which the transept of Beverley Minster, and the order of Salisbury Cathedral were beautiful illustrations. So in every other architecture, and informs of all kinds. In fact, from the long and the short, the dactyle and spondee, hexameter and pentameter, sapphics and iambics, the very term ευρυθμια (proportion), used by the Greeks, was derived.

Under the fifth head, Consistency, lib. i. c. 2, Vitruvius tells us, that circumstance, custom, or fitness, and nature are to guide us. Temples to Jupiter Cœlus, the sun and moon, are to be hypethral, because these divinities are known to us by their continual presence night and day. Doric temples are to be erected to Minerva, Mars, and Hercules, on account of their masculine character; Corinthian is proper to Venus, Flora, Proserpine, &c.; Ionic, as the medium order, is applicable to Juno, Diana, and Bacchus; all these, says he, bear an *analogy* to the dispositions of the deities.

Again, in lib. iii. c. 1, he says, "the design of temples depends on symmetry, the rules of which architects should be most careful to observe; symmetry arises from proportion, which the Greeks call αναλογια." He then proceeds to describe the proportions of the human figure in detail, and remarks its correspondence with the geometrical figures, the square and the circle; even the measures used in buildings, the digit, the palm, the foot, the cubit, called by the Greeks τελειος, prove the analogy of architecture (continues he) with the human proportions.

In lib. iv. c. 1, Vitruvius describes the origin of the Doric, Ionic, and Corinthian orders, as derived from the proportions of the man, the matron, and the damsel, by analogy; and although these analogies have been regarded by some as fanciful, their æsthetical propriety is more intelligible to the artist, than their definition by language to the logical reader. For instance, the ancient Doric, from five to six diameters in height, though low in its proportions, assumes a dignity in its concentrated strength and solidity, its rapid diminution, and its wide-spreading cap, which no one who has viewed it at Pæstum and at Corinth can ever forget.

When Homer describes Priam as identifying the Grecian leaders from the walls of Troy, he is made to inquire of Helen—

> What's he whose arms lie scattered on the plain;
> *Broad in his breast, his shoulders larger spread,*
> Though great Atrides overtops his head?

Had Homer (always a painter) confined his description to the stoutness and the shortness of Ulysses, we should have been at a loss for his heroic dignity; he might have been a tub or an alderman, but the "broad shoulders and spreading breast" imply the rapid diminution of the waist, and the same healthful and vigorous character through every limb; and Ulysses stands before us in all the energy of the Grecian hero—

> Though some of larger stature tread the green,
> *None match his grandeur and exalted mien!*

no such peculiarity is attributed to "the great Atrides;" the tall is not compatible with this rapid diminution: whenever these qualities, therefore, are affected, as in the Parthenon, the temple of Nemea, or in the Roman Doric, the upper diameter bears a larger proportion to the lower. So in the matronal or the medium proportion, the gradation of form is much smaller; and in the juvenile Apollo or the young damsel, the diminution of the limbs is still less observable; and the Ionic or the Corinthian are proportioned accordingly. In the details the same analogy is observed; the mouth, the eye, and the features of the Hercules are as susceptible of delicacy as the Doric echinus is of its small fillets and its fine contour.

The matronal or medium demands a sober ornament, and the Corinthian all the young elegance which the acanthus and the graceful Lesbian profile can communicate.

Thus the tall, the short, and the slender, are all types of proportion in their proper places; their *excess* makes them the awkward and ungainly, the clumsy and shapeless, and the thin or meagre; and there is no other course by which they can be rightly embodied, than by the careful and intelligent observation of those types, as exhibited in the works of nature—in the animal and vegetable kingdoms.

In this respect taste, like wit, consists in discovering resemblances and unexpected congruities.

The history of the works of genius illustrates abundantly the reference to analogy in the science as well as in the art of architecture. Smeaton, in his work on the Light-House at Eddystone, after describing the former ones, and showing their defects, proceeds to explain his original conception of that celebrated work. "On this occasion," says Smeaton, "the natural figure of the waist or bole of a large spreading oak presented itself to my imagination. Its top, when full of leaves, is subject to a very great impulse from the agitation of violent winds; yet partly by its elasticity, and partly by the natural strength arising from its figure, it resists them all, even for ages. It is rare that we hear of such a tree being torn up by the roots. Let us now consider its particular figure. Connected with its roots, which lie hid below ground, it rises from the surface thereof with a large swelling base, which at the height of one diameter is generally reduced by an elegant curve, concave to the eye, to a diameter less by at least one-third, and sometimes to half, of its original base. From thence its taper diminishing more slow, its sides by degrees come into a perpendicular, and for some height form a cylinder. Now, we can hardly doubt but that every section of the tree is nearly of an equal strength in proportion to what it has to resist; and were we to lop off its principal boughs, and expose it in that state to a rapid current of water, we should find it as much capable of resisting the action of the heavier fluid, when divested of the greatest part of its clothing, as it was that of the lighter when all its spreading ornaments were exposed to the fury of the wind. And hence we may derive an idea of what the proper shape of a column of the greatest stability ought to be, to resist the action of external violence, where the quantity of matter is given whereof it is to be composed."

Sir C. Wren has given another fine example of this kind of analogy. In the vast practice which the fifty churches of this metropolis and the examination of all the authorities which he had occasion to consult had given him, he reflected that the hollow spire which he had seen or built in so many varieties was after all but an infirm structure; and he sought that model which should enable him to impart to it the utmost solidity and duration. Simple was the original from which he adopted his idea. He found that the delicate shell called turretella, though extremely long, and liable to fracture from its base to its apex, by the action of the water amidst the rocks, was rendered impregnable by the central column, or newel, round which the spiral turned. Therefore, in his spire of St. Bride's, he establishes the columella in the centre, round which he forms a spiral staircase to the top, issuing on stages of arched apertures: thus giving us (if not the most beautiful) certainly the most remarkable and enduring of any spire hitherto erected.

One more instance equally remarkable may be given. When Brunelleschi was charged with the erection of the dome of Sta. Maria, at Florence, of nearly equal diameter with that of the Pantheon, but at more than twice its height from the pavement, upon a base raised on piers, and by no means of the strength and cohesion of the original model, the Pantheon, it was apparent that in giving it the same solidity, the weight would be insupportable on such a foundation. How was this object to be accomplished? Brunelleschi was an observer of all nature's productions, and he reflected that the bones of animals, especially of birds, possessed solidity without weight, by the double crust and hollow within. But above all, he remarked that the dome which completes the architecture of the human form divine was constructed with a double plate, connected by the light and fibrous, but firm walls of the hollow cancelli, so that strength and lightness were combined in the utmost degree. Brunelleschi followed this model in his dome of Sta.

body onward; the effort of the animal being resolvable into these two parts —viz. the action on the load, and that required to move itself by. It may be gathered from writers on this subject that the force a horse is capable of exerting, is that equal to about one-seventh or one-eighth part of his own weight: or that, on an ascent of one in seven or one in eight, the exertion required to overcome his own gravity, is a force equal to that he is able to exert on a load on a level plane. Taking the average weight of a horse, and considering that he is capable of occasionally exerting great extra power on the load, still it seems to be satisfactorily ascertained, that nearly seven parts out of eight of the muscular power of a horse is required to drag his own weight forward, leaving, of course, only one part applicable to the load. But the criterion of a horse's power in practice is not the occasional effort of which the animal is capable at a dead pull, or for a short period: we must estimate his strength by what he can do daily, and day after day for a long period, and without breaking him down prematurely. If a horse is to travel at the rate of 10 miles an hour, his power of pulling is greatly diminished, and he can work only an hour or so in the day: at two miles an hour he may give out a power of 150 lb. on the load: at 10 miles he has scarcely 35 lb. to spare, and at 12 miles an hour, he can seldom be expected to do more than move himself. This was on the average of horses—all beyond were exceptions. Thus, the application of horses to railways as the motive-power was very limited: and in laying out lines where they are to be used, to full effect, gravity should be arranged to be always with the load, or, at least, not against it: the rate of travelling only 2 or $2\frac{1}{2}$ miles per hour, and the traffic uniform. Mr. Vignoles proceeded to an interesting comparison between locomotive and stationary power up inclined planes, taking the inclination of 1 in 50 as a maximum, and showed that *when the traffic was small, and the loads consequently comparatively light, and the daily number of trains not great, locomotive engines*, as the motive-power, (taking into consideration all circumstances of first cost, and working expenses—particularly the latter, of which the locomotive power was but a small part), *would not be so expensive as stationary engines*, while they would be certainly more convenient; and that, with all the best modern improvements in the locomotive engines, the system of working with large cylinders, using the steam expansively on the level and falling parts of the railway, improved boilers, &c., *planes of 1 in 50 might be practically worked*: the only material drawback being, occasional slipping of the wheels on the ascent, and the necessity of great caution and careful application of the brakes on descents; but on the whole, the balance, *under the above circumstances*, was much in favour of the locomotive system. The Professor then entered into a very long and minute comparison of the present system of working the Blackwall Railway by stationary engines, with ropes and pullies, with what would be the case if the motive power were locomotive engines—and by tables, showed that while the working of the Blackwall Railway ($3\frac{1}{2}$ miles) on the stationary system, was costing about *seventy-two pence* per mile per train, the cost of working the Greenwich Railway ($3\frac{3}{4}$ miles) was only about *forty pence*:—but, Mr. Vignoles admitted, that by the former, great accommodation to the public was afforded by the numerous intermediate stations, while on the latter, there was only one stoppage. In concluding the general comparison between the two principles of mechanical motive-power, the Professor observed that on the locomotive system, a minimum of power need only be provided in the first instance and the number of engines might be increased gradually as the traffic required, which was a great consideration when the first expenditure of capital had to be kept down to the very lowest terms, at all future risks. On the stationary system, provision had to be made, from the outset, for the maximum anticipated trade, which of course increased the first outlay on the railway establishment, and depended on the ultimate economy of future working to make up the difference. Having concluded the notice of various descriptions of *motive-power* employed on railways, of which the preceding is but a mere outline, some general remarks were made on the principles of laying out railways, in reference to the several systems respectively.

In a concluding general summary, Mr. Vignoles observed, that in his first course, at the latter end of 1841, he had fully considered the practical rules for earthwork and constructions:—these were not peculiar to railways, the theory and practice of bridge-building, applied to all internal communication, and would be most conveniently considered in a separate illustrated course, but he wished to recall to the class generally, that in proceeding to lay out railways in the first instance, the engineer ought to enter much more deliberately into those previous inquiries, so absolutely necessary, than had hitherto been done. A system of applying the same general rule of perfect gradients alike to lines, of the least as well as of the greatest traffic, had too much prevailed, and until more rational ideas were substituted, the public would shrink from embarking in enterprises subject to all the contingencies of extra cost beyond estimates which had characterised almost every railway in this country. *The earthwork and its consequences*, regulated the cost, particularly as regarded contingencies, and the utmost consideration should be bestowed as to how far it was justifiable to encounter the expense of these operations. The average cost of earthwork, and all consequent works of art, &c., on the English railways was nearly £15,000 per mile, or about 50 per cent. of the whole capital expenditure. Mr. Vignoles was decidedly of opinion that *in all future lines in this country, and particularly on the continent*, the corresponding outlay *ought not to exceed £5000 per mile*, and that beyond that sum perfection of gradient would be bought too dearly. In reference to the *gauge* of railways, Mr. Vignoles stated, distinctly, that theoretical investigations and practical results led him to consider a six foot gauge the best; but the present $4\frac{3}{4}$ foot gauge was certainly rather cheaper. In respect of *curves*, he observed, that they were much less disadvantageous than had been first supposed: that a half mile radius was now everywhere admitted: and that he himself did not hesitate to adopt a quarter mile radius whenever expense could be materially saved; and if the atmospheric system of motive power should be found to succeed on a large scale, the curves might, on lines thus worked, be safely made still sharper. In regard to the systems of constructing the *upper works*, he had in a recent lecture, entered so fully into the comparison, that he need only now say, that if the expensive and complicated system of heavy rails and chairs, and cross sleepers, were preferred by engineers, then the ingenious improvements of Mr. May, of Ipswich, in chairs and fastenings, applied by Mr. Cubitt on the South Eastern (Dover) Railway, with great care in laying, draining, and ballasting, made *that system* perfect and complete. The Professor, however, decidedly gave the preference to the less costly, and the more simple system of lighter rails, without chairs, laid on continuous longitudinal balks of timber of sufficient scantling, and fastened on Evans's principle, modified in the manner shown by the models exhibited to the class; and several engineers were adopting this opinion. On the continent of Europe, where iron was dear, and timber cheap and abundant, Mr. Vignoles calculated *a saving of full £2000 per mile of double road would accrue from the adoption of the latter system*—which offered a vast national economy. In reference to the subject of working drawings, plans, and sections, the Professor reminded the class of the importance he attached to having all such previously made out on a large scale, that the cubic quantities might be accurately obtained, and the just prices considered; and thus, in proceeding to make the estimates, nothing would be left to conjecture, and as little as possible left to be afterwards altered. The period of time for the execution of the works should be extended as far as consistently could be done. The two great sources of the extra expenditure on railways had been, the extreme haste with which the works had been pushed on, and the changes of every kind from the original designs. These points being all carefully considered, *even before the plan was brought before the public in general*, the estimates might be better depended on. Mr. Vignoles then went through all the great items of expenditure generally arising on first construction, and explained how the accounts of measurements should be made out and kept under very distinct general heads, subdivided into minor items, from the purchase of the land to the last finish to the stations, and the entire fitting up and furnishing of the carrying establishments. Sufficient experience had been attained in all these matters to enable the engineer, in future, if the above rules were faithfully followed out, to place himself beyond all chance of reproach for making erroneous estimates. In conclusion, the Professor observed, that he had selected *railways* at the request of the class, as the theme for the course just concluded; but although so much consideration had been given to the subject, he had only been able to touch in a very general way upon the chief points; yet it was to be hoped a sufficient idea had been given of the principles of construction, and of their general application, to create an interest in their minds. Should any of the students hereafter be employed to execute a railway, he trusted they would recollect these lectures with advantage, while they would also probably better understand and appreciate them: at the same time, he must not neglect to impress upon them, that it was not at the college, in the lecture-room, or even in the office of an engineer, that all the duties and knowledge necessary could be taught: the young aspirant must pass much time in the work-shop, indeed, he must become a workman, and acquire the use and skill in the handling of tools, and the erection of mechanism of every kind—and passing to the actual works, ought to learn to be able to direct personally the labour of the mason, the carpenter, and the smith. "Above all," said Mr. Vignoles, "the student in engineering must carry into life with him the constant remembrance of what I have so repeatedly enforced, that the reputation of an engineer in this country is based upon the success of his works, of his mechanism, and of all the efforts of his mind and hand, in respect to, and in proportion to their being productive of commercial and beneficial results, to those who, at his suggestion, may undertake to provide the necessary funds: and he should consider how this result can be best obtained, rather than study the splendour of his undertakings. It is for the architect to attend to the decorative and the beautiful; it is sufficient for the engineer to study proportions, and rely on the simple grandeur of his works as a whole. It is related that Napoleon once observed to the celebrated Carnot, "*Les ingenieurs doivent toujours avoir des idées magnifiques*;" this is true as to their first conceptions, but in the realization, they must be sobered down by the rules of economy and judgment. After the first burst of talent, after image and form has been given by the hand to the bright idea emanating from the brain, let it be brought down to practical application only after a strict inquiry into the cost. Remember what I quoted on a former occasion, when contrasting the two celebrated light houses, the *Eddystone*, and the *Cordouan*—no unfit emblem of the two celebrated engineers who erected them may I venture to add of their respective nations—remember, I say, "*'tis use alone that sanctifies expense.*"

ROYAL ACADEMY.

Professor Cockerell's Lectures on Architecture.

(From the Athenæum.)

Lecture V.

The love of fine art, and the lively discussion of its principles, which occupied the wits and the courts of Italy in the 15th and 16th centuries, employed the solitary reflections of literary philosophers in the 18th; and in 1730, Baumgarten suggested the title of æsthetics, by which these studies have been designated ever since, and many works remarkable for ingenious criticism, learning, and taste, have resulted. These may be ranked in two classes. The first resolves the questions of taste directly into an original law of our nature, implying senses by which the qualities of beauty and sublimity are perceived and felt as their appropriate objects; it is this species of hypothesis to which artists and amateurs chiefly resort. The second class of hypothesis arises from the opposite view of the subject: resisting the idea of any new and peculiar sense distinct from the common principles of our nature, this class supposes some one known and acknowledged principle or affection of the mind to be the foundation of all the emotions we receive from the objects of taste, and resolves them into some more general law of our intellectual or moral constitution. Thus Socrates and Hume, and others, resolve them into our sense of utility—Aristotle and St. Augustine, into order and design—Diderot and Allison into relation and association. But though in such discussions we recognize many truths, the partiality of individual views renders them often dangerous.

> When a philosopher can find
> Some fav'rite system to his mind,
> In every point to make it fit,
> He'll force all nature to submit.

Language itself fails in defining those phenomena which elude ordinary observation, and even when it approaches definition, the measure of quantity, and quality, and circumstance, can alone be adjusted by the magician genius.

The æsthetical principles of architecture, as handed to us from the Greeks by Vitruvius, concur with the notions of ancient philosophy, and have not been controverted by the modern; and though subjected of late years to some rude attacks, they have never been superseded, and we can follow no better text-book in the consideration of our subject. Those principles apply to every style and invention of architecture which the world has hitherto known; they belong to our physical and intellectual nature, and will never change but with an alteration in these.

When the works of Vitruvius were first discovered, they were accounted a revelation to the craft, and called "divine" by Sulpitius, the first translator; and, nearly 200 years after, Perrault, in his translation, calls them "a very singular piece, and an inestimable treasure in the opinion of the learned." Eighteen translations, in 41 editions, are enumerated to this day. In 1807 the philologist Schneider republished Vitruvius. "My whole scope," says he, "has been to purify the text, so as to enable men learned in art to reconstruct and understand the theories of Vitruvius, hitherto obscured by interpolations and vicious translations." But he detracts from the merit of his work by a severity of criticism, as uncandid as it is derogatory to the character of his author. He declines his apology, as "writing neither as an accomplished philosopher, an eloquent rhetorician, nor as an expert grammarian, but as an architect, laying down rules useful to those who build." He calls his language obsolete and plebian, accuses him of pride and envy, and rates him as a morose, inept, infirm old man, querulous and vulgar. But Schneider was the less justified in such treatment, as being weak upon those points in which his author was most strong, for he says, "on architectural subjects, or that which has to do with the subtleties of the art, and the questions and disputes concerning them, I neither could nor would have anything to say." So that the science has received no direct advantage from the labours of Schneider, and yet how much was to be done might be understood by ten discoveries in confirmation of the theories of Vitruvius, made within a few years, and chiefly by Englishmen, cited by the Professor in his previous course on the literature of the art. Such discoveries suggested the desirableness of a new English edition of Vitruvius, as highly honourable and useful to this country. The last, by Mr. Gwilt, is a very useful one.

The slanders of Schneider had been adopted in this country with little honour to the parties, and no advantage to architecture. Vitruvius remained the father of our art, and was entitled to our respect, as the text-book of our studies.

Having been appointed surveyor to the warlike engines and stores of the empire by Augustus, Vitruvius was endowed with leisure; and very probably was instructed to collate the Greek authors on our art, whom he enumerates, and who were collected and deposited in the magnificent library instituted at that period. He appears then with singular advantage as transmitting the well digested and received principles of the greatest masters who had thought and written on architecture, to modern times; and the principles thus derived directly from the Greeks merit our closest attention.

But a few preliminary observations on external forms, in detail and in general, were to be made. The universality of certain primordial forms in all styles, favours the notion of innate ideas, the cube, the sphere, the ellypsoid in solids; the lozenge, the wave, cymarecta, and cymareversa, the serpentine, the ovalo, the spiral, the volute, gradation or diminution of forms, are common to the art of all times and people.

The pyramid is universal, from the compressed to the acute. Such is the charm of the pediment, that "in heaven, where we may not suppose it to rain," says Cicero, "the pedim nt will surely be found;" so in mountains, trees, and fixed bodies, in which the laws of statics are observed, the pyramid prevails; except in those forms in which dynamics demand a different structure. The pyramidal inclination of the sides of buildings observed in Egyptian, Hindoo, Gothic, and Mexican architecture, has, by the happy discoveries of late years, been proved to exist in Greece also; and the inclination of the axis of the columns at the sides of temples (enjoined by Vitruvius, lib. iii. c. 3, long disputed,) is now beyond all doubt, and the pyramidal inclination to building is proved to be an universal principle.

Gradation of columnar forms, as in the limbs of animals, and in vegetable productions, is universally approved; the cylinder, the leg of an elephant, are justly repudiated: "small by degrees, and beautifully less," has been denied by an eminent critic (P. Knight), "because," says he, "the same is large by degrees, and beautifully bigger;" but however smart the reply, it does not controvert the principle. It is, however, to be observed, that such forms should diminish *from the eye*, as a column does above the horizon, and the leg of a chair or table below it.

The Doric cymatium, the cymareversa, the ovalo, the cavetto, or hollow, are all calculated to express strength, as robust, and appearing to sustain. The Lesbian cymatium, the cymarecta, in all its varieties, has not the same purpose, (namely, to sustain,) and is suited to the more elegant orders. The principle of the application of mouldings for beauty, is the opposition of the curved to the straight surfaces, as well for light and shade as form; and for proportions and oppositions of such forms, constitute the art of profile—a most difficult grace of architecture; for by this, that variety of form and grace may be given which the primary architectural masses and proportions do not admit of. Variety in the *details of sculpture and profile is essential* to the relief of that rigorous geometrical order, which the larger features of architectural composition impose: in all the arts, and even in architecture, variety is an all-important principle, provided the masses are undisturbed. Shakspeare describes Cleopatra as chiefly admirable for this quality:

> Age cannot wither her, nor custom stale
> Her infinite variety.

The Greek profile is general (more particularly in the Parthenon) is incalculably superior to any other in gradation, quantity, delicacy, and expression, and should be the student's constant study. It was the observation of the human, animal, and vegetable forms, by the sculptors of Greece, which gave them that acknowledged superiority. The enrichment of these with homogeneous ornament, was no less remarkable, and deserves an especial treatise. In fact, the elements of architecture, in the orders and their profile, constitute the peculiar excellence of Greek architecture, which, as we have seen in history, did not extend to the composite and voluminous combinations which subsequent ages adopted.

Having thus adverted to individual forms as applied to detail, the Professor remarked upon general forms, as applied to the composition of buildings. The observations already offered upon the ancient system of building "in large stones and costly stones, even great stones," doubtless contributed much to the universal adoption of horizontal forms of building. But this tendency, thus imposed by the mechanical construction, seems also to have been an abstract principle of taste, which was consulted best by the contrast of the long horizontal form, with the (generally) vertical outline of the country in which they were employed. When the traveller, passing through a mountainous region of rugged outline, discovers through some gap the horizon of an extended plain, or of the ocean, a sublime sensation is experienced. In such a country the rocks and mountains afford elevations compared with which the works of man are insignificant. The temple is planted on the precipitous eminence, and it attains at once the elevation of St. Peter's or St. Paul's. So placed, the Doric members should be massive, simple, and few; the parts broad; it seems to have grown spontaneously from its rocky bed, and to partake in its monolithic masses of the stony aboriginal material on which it is established. Its horizontal outline and regularity of order are admirably calculated to contrast with the surrounding scenery of vertical and irregular forms.

On the other hand, when the road winds through interminable plains, the traveller recognizes the sublime in the contrast of vertical forms of architecture; for this reason, it may be presumed, the Babylonians in the plains of Assyria, proposed to "build a city and a *tower* whose top may reach unto the heavens." In the flats of Venice, in the Netherlands, in the champains

Maria (in the manner displayed in a large section exhibited); and the traveller now ascends to the lantern between the two crusts or plates forming the inner and the outer domes.

Michael Angelo adopted this contrivance in the dome of St. Peter's; and almost all the subsequent domes are upon the same idea.

The Professor pointed out these instances of analogy as sufficient to show that the architect might thus avail himself of the whole range of Nature's works; and that the universe furnished him the inexhaustible models from which his inventions might be drawn.

REVIEWS.

THE ANCIENT RUINS OF YUCATAN.

Rambles in Yucatan. By B. M. Norman. New York: 1843.

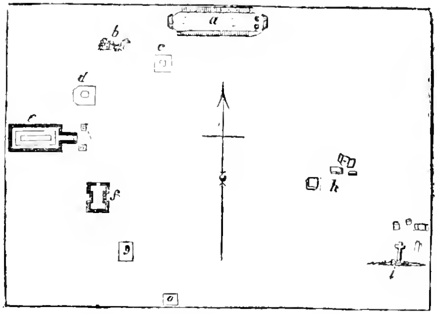
The last quarter of a century has been distinguished by the scientific and successful researches which have been made into the material and moral world of unrecorded ages. What the far-seeing predicted, but hardly hoped would occur, what the visionary exhausted himself in vain efforts to ascertain, has now taken place; the film, the mist which concealed and disfigured the unknown past, is giving way before the labours of men of science, and the long-hidden forms of antiquity's infancy are becoming revealed to our eyes: while the progress made is such that we can scarcely doubt of a glorious harvest of discovery in the end. While geology and palæozoology have shown us the rudiments of the physical world, portrayed its vegetation, and pictured the creatures which inhabited it, philology and paleætiology have thrown glorious light upon the early history of the human race. While geology was pursued on a false system, and theories were formed before facts were accumulated, its votaries were the derision of the world; nor did the philologists suffer less deservedly: their wild speculations drew from Voltaire the definition that their science was one in which "*la consonne y entrait pour fort peu de chose et la voyelle pour rien*:" and Goldsmith sarcastically determines from the resemblance of the letters, that Con-fu-ci-us and Noah were the same personages. This time, however, has now passed, and both geology and philology, studied upon the principles of Bacon, have become fixed sciences. From philology has sprung paleætiology, or the science of applying philological evidence to the history of the human races, and Bopp, Pott, Raske, Prichard, Winning, and others have successfully laboured in this department. In connection with these studies is that of the early monuments of art, the elucidations of which in Egypt, in Iranistan, in India, and America, deeply engage the attention of men of science. If in the old world we are astonished at the gigantic records of ancient civilization, we were totally unprepared to find the new continent as rich in these memorials as our own. Records of a race which seems to have "died and left no sign," works without a name, monuments bearing the impress of the fathers of civilization in India and Egypt—they are calculated to awaken the deepest interest, and to enlist the strongest sympathy of the artist and the scholar. Humboldt and Lord Kingsborough prepared the way in the study of Mexican antiquities, which Waldeck, Stephens, and Norman have followed out: and the result is, the opening a field of study in Yucatan, rich in architectural and artistical interest.

For a copy of Mr. Norman's work, we have been indebted to the kindness of Messrs. Wiley and Putnam, and we proceed to give some account of it and its author. Mr. Norman was led to Yucatan in a chance excursion in the autumn of 1841, and commenced his researches with no other instrumental aid than a knife and pocket compass, and pencil and paper; yet, although he pretends to no scholarship, he has produced a work, containing minute descriptions of the ruins, with many notes derived from the works of his predecessors. He seems to have been an active and energetic observer, and to have gone about his task with all that poco-curantism for trifles, which the wanderer in Spanish countries must possess if he would make himself happy and useful. Mr. Norman's journal contains descriptions of the manners and customs of the people, as well as accounts of the ruins, which were the more especial objects of his visit.

Yucatan, we need scarcely remind our readers, is a peninsula, remarkable for running from south to north, bounded on the east by the English settlement of Honduras, on the south by Guatimala, and on the south-west by Mexico, of which it was recently a province, although now independent. The west coast is known to us as the Campeachy shore, and was the scene of many an exploit in the logwood-cutting times of the early part of the seventeenth century. The country itself presents but little to interest us in its modern state, but in the northern parts have been discovered the ruined cities of Uxmal, Kabah, Zayi, Ticul, Sisal, Chi-Chen, and Espita; and it will be observed that not more than a third of the country has been as yet imperfectly explored, while what the mountain regions of the interior may present is unknown. The inhabitants are chiefly of Indian descent, called Mayas, of whom we shall speak again hereafter.

Leaving Mr. Norman to speak for himself, the first place to which he leads us is Chi-chen, of which a plan is shown below.

Fig. 1.—Plan of the Ruins of Chi-Chen.



a, temple; *b*, ruins; *c*, pyramid; *d*, dome; *e*, house of the Caciques; *f*, house; *g*, hacienda; *h*, evidences of large and splendid structures; *i*, cross erected by the Indians; *o*, church of the Indians.

"It was on the morning of the 10th of February that I directed my steps, for the first time, toward the ruins of the ancient city of Chi-Chen.[1] On arriving in the immediate neighbourhood, I was compelled to cut my way through an almost impermeable thicket of under-brush, interlaced and bound together with strong tendrils and vines; in which labour I was assisted by my diligent aid and companion, José, I was finally enabled to effect a passage; and, in the course of a few hours, found myself in the presence of the ruins which I sought. For five days did I wander up and down among these crumbling monuments of a city which, I hazard little in saying, must have been one of the largest the world has ever seen. I beheld before me, for a circuit of many miles in diameter, the walls of palaces and temples and pyramids, more or less dilapidated. The earth was strewed, as far as the eye could distinguish, with columns, some broken and some nearly perfect, which seemed to have been planted there by the genius of desolation which presided over this awful solitude. Amid these solemn memorials of departed generations, who have died and left no marks but these, there were no indications of animated existence save from the bats, the lizards, and the reptiles which now and then emerged from the crevices of the tottering walls and crumbling stones that were strewed upon the ground at their base. No marks of human footsteps, no signs of previous visitors, were discernible; nor is there good reason to believe that any person, whose testimony of the fact has been given to the world, had ever before broken the silence which reigns over these sacred tombs of a departed civilization. As I looked about me and indulged in these reflections, I felt awed into perfect silence. To speak then, had been profane. A revelation from heaven could not have impressed me more profoundly with the solemnity of its communication, than I was now impressed on finding myself the first, probably, of the present generation of civilized men walking the streets of this once mighty city, and amid

'Those temples, palaces, and piles stupendous,
Of which the very ruins are tremendous.'

For a long time I was so distracted with the multitude of objects which crowded upon my mind, that I could take no note of them in detail. It was not until some hours had elapsed, that my curiosity was sufficiently under control to enable me to examine them with any minuteness."

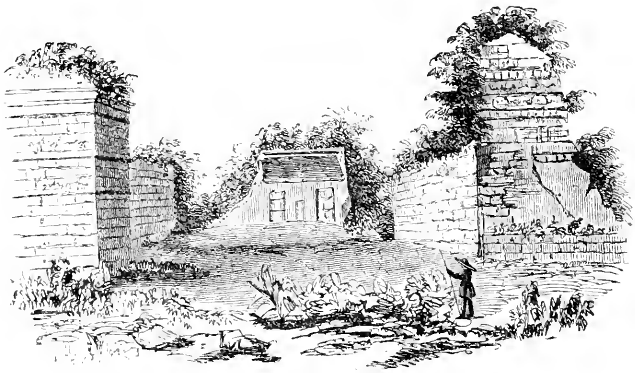
"My first study was made at the ruins of the Temple.[2] These remains consist, as will be seen by reference to the engraving (*a*, Fig. 3, & Fig. 1), of four distinct walls. I entered at an opening in the western angle, which I conceived to be the main entrance; and presumed, from

"[1] Chi-Chen signifies, mouth of a well. 'Itza,' said to be the Maya name for one of the old possessors of these ruins, is sometimes added by the natives.

"[2] The names by which I have designated these ruins, are such as were suggested to me by their peculiar construction, and the purposes for which I supposed them to have been designed.

the broken walls, ceilings, and pillars still standing, that the opposite end had been the location of the shrine or altar. The distance between these two extremes is 4[illegible]0 feet. The walls stand upon an elevated foundation of about 16 feet. Of the entrance, or western end about one-half remains: the interior showing broken rooms, and ceilings not entirely defaced. The exterior is composed of large stones, beautifully hewn, and laid in fillet and moulding work. The opposite, or altar end, consists of similar walls, but has two sculptured pillars, much defaced by the falling ruins—six feet only remaining in view above them. These pillars measure about two feet in diameter. The walls are surrounded with masses of sculptured and hewn stone, broken columns, and ornaments, which had fallen from the walls themselves, and which are covered with a rank and luxuriant vegetation, and even with trees, through which I was obliged to cut my way with my Indian knife. In the rear of the pillars are the remains of a room, the back ceilings only existing: sufficient, however, to show that they were of rare workmanship.

Fig. 2.—The Temple—Chi-chen Ruins.



"The southern, or right hand wall, as you enter, is in the best state of preservation, the highest part of which, yet standing, is about 50 feet: where, also, the remains of rooms are still to be seen. The other parts, on either side, are about 2[illegible] feet high, 250 long, and 1[illegible] thick, and about 130 apart. The interior, or inner surface of these walls, is quite perfect, finely finished with smooth stone, cut uniformly in squares of about two feet. About the centre of these walls, on both sides, near the top, are placed stone rings, carved from an immense block, and inserted in the wall by a long shaft, and projecting from it about four feet. They measure about four feet in diameter, and two in thickness—the sides beautifully carved.

"The extreme ends of the side walls are about equi-distant from those of the shrine and entrance. The space intervening is filled up with stones and rubbish of walls, showing a connexion in the form of a curve. In the space formed by these walls are piles of stones, evidently being a part of them: but there were not enough of them, however, to carry out the supposition that this vast temple had ever been enclosed. At the outer base of the southern wall are the remains of a room; one side of which, with the angular ceiling, is quite perfect, measuring 11 feet long and [illegible] wide. The parts remaining are finished with sculptured blocks of stone of about one foot square, representing Indian figures with feather head-dresses, armed with bows and arrows, their noses ornamented with rings; carrying in one hand bows and arrows, and in the other a musical instrument similar to those that are now used by the Indians of the country. These figures were interspersed with animals resembling the crocodile. Near this room I found a square pillar, only five feet of which remained above the ruins. It was carved on all sides with Indian figures, as large as life, and apparently in warlike attitudes. Fragments of a similar kind were scattered about in the vicinity.

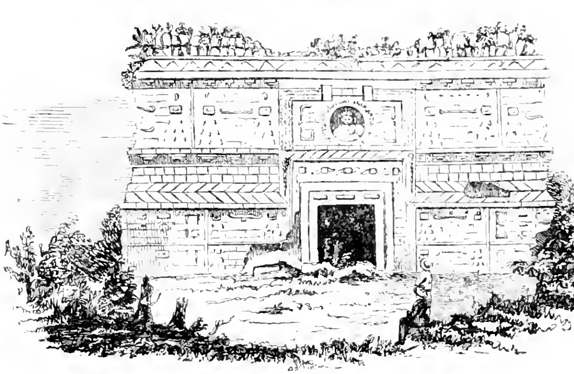
"From this room, or base, I passed round, and ascended over vast piles of the crumbling ruins, pulling myself up by the branches of trees, with which they are covered, to the top of the wall: where I found a door-way, filled up with stones and rubbish, which I removed, and, after much labour, effected an entrance into a room measuring 8 by 24 feet, the ceiling of which was of the acute-angled arch, and perfected by layers of flat stones. The walls were finely finished with square blocks of stone, which had been richly ornamented. Even yet the heads of Indians, with shields and lances, could be distinguished in the colouring.

"The square pillars of the door-way are carved with Indians, flowers, borders, and spear-heads; all of which I judged to have once been coloured. The lintel, which supported the top, is of the zuporte wood, beautifully carved, and in good preservation. One of the Indian head-dresses was composed of a cap and flowers.

"Immediately in front of the door-way is a portion of a column, to which neither cap nor base was attached. It measured about three feet in diameter, with its whole surface sculptured: but it was so obliterated by time, that the lines could not be traced. Four feet of its length only could be discovered. It was, evidently, imbedded in the ruins to a great depth. Numerous blocks of square hewn stones, and others, variously and beautifully carved, were lying in confusion near this column.

"Of the exterior of these walls, a sufficient portion still exists to show the fine and elaborate workmanship of the cornices and entablatures, though the latter are much broken and defaced. They are composed of immense blocks of stone, laid with the greatest regularity and precision, the facades of which are interspersed with flowers, borders, and animals."

Fig. 3.—The front of the House of the Caciques—Chi-Chen Ruins.



"I cut my way through the thick growth of small wood to the House of the Caciques, and by the aid of my compass was enabled to reach the east front of the building. Here I felled the trees that hid it, and the whole front was opened to my view, presenting the most strange and incomprehensible pile of architecture that my eyes ever beheld—elaborate, elegant, stupendous, yet belonging to no order now known to us. The front of this wonderful edifice measures 32 feet, and its height 2[illegible], extending to the main building 50 feet. Over the door-way, which favors the Egyptian style of architecture, is a heavy lintel of stone, containing two double rows of hieroglyphics, with a sculptured ornament intervening. Above these are the remains of hooks carved in stone, with raised lines of drapery running through them; which, apparently, have been broken off by the falling of the heavy finishing from the top of the building; over which, surrounded by a variety of chaste and beautifully executed borders, encircled within a wreath, is a female figure in a sitting posture, in basso-relievo, having a head-dress of feathers, cords, and tassels, and the neck ornamented. The angles of this building are tastefully curved. The ornaments continue around the sides, which are divided into two compartments, different in their arrangement, though not in style. Attached to the angles are large projecting hooks, skilfully worked, and perfect rosettes and stars, with spears reversed, are put together with the utmost precision.

"The ornaments are composed of small square blocks of stone, cut to the depth of about one to one and a half inches, apparently with the most delicate instruments, and inserted by a shaft in the wall. The wall is made of large and uniformly square blocks of limestone, set in a mortar which appears to be as durable as the stone itself. In the ornamental borders of this building I could discover but little analogy with those known to me. The most striking were those of the cornice and entablature, *chevron* and the *cable* moulding, which are characteristic of the Norman architecture.

"The sides have three door-ways, each opening into small apartments, which are finished with smooth square blocks of stone; the floors of the same material, but have been covered with cement, which is now broken. The apartments are small, owing to the massive walls enclosing them, and the acute-angled arch, forming the ceiling. The working and laying of the stone are as perfect as they could have been under the directions of a modern architect."

Another description we take from him is that of the ruins of Zayi.

"The Ruins of Zavi are situated in the midst of a succession of beautiful hills, forming around them, on every side, an enchanting landscape.

"The principal one is composed of a single structure, an immense pile, facing the south, and standing upon a slight natural elevation. The first foundation is now so broken that its original form cannot be fully determined; but it probably was that of a parallelogram. Its front wall shows the remains of rooms and ceilings, with occasional pillars, which, no doubt, supported the corridors. The height of this wall is about 20 feet, and, as near as I was able to measure around its base, (owing to the accumulation of ruins,) it was ascertained to be 268 feet long, and 116 wide.

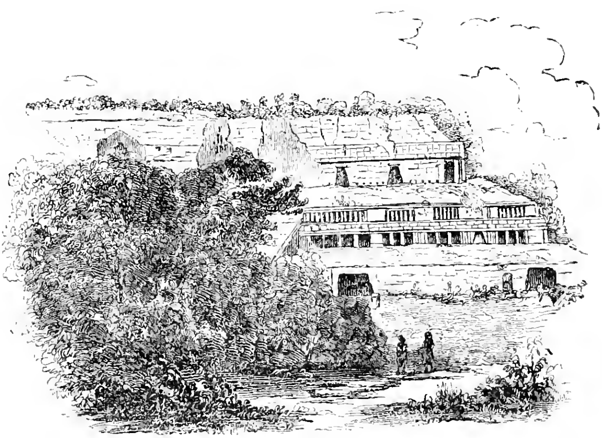
"In the centre of this foundation stands the main building, the western half only remaining, with a portion of the steps, outside, leading to the top. This part shows a succession of corridors, occupying the whole front, each supported by two pillars, with plain square caps and plinths, and intervening spaces, filled with rows of small ornamented pillars. In the rear of these corridors are rooms of small dimensions and angular ceilings, without any light except that which the front affords. Over these corridors, or pillars, is a fine moulding finish, its angle ornamented with a hook similar to those of Chi-Chen. Above this moulding is a finish of small plain round pillars, or standards, interspersed with squares of fine ornamental carvings; the centre of the façade showing the remains of more elaborate work, concentrated within a border, the arrangement of which is lost. There is an evident analogy existing between these ornaments and those of Kabbah, but order is less apparent. I could discover no resemblance whatever to those of Chi-Chen.

"Over these rooms of the main building is another terrace, or foundation, in the centre of which is a building in similar ruins to those under it; having, also, broken steps leading to the top. It stands upon a foundation, apparently, of six to eight feet in height, occupying about two-thirds of the area; the residue, probably, forming a promenade. There are three doorways yet remaining, the lintels and sides of which are broken, and which have caused the walls above to fall down. The walls of this part of the edifice are constructed of hewn stone, without any signs of ornament. A plain finished moulding runs through the centre; portions of the cornice still remain, with three or four pieces of flat projecting stones, which formed a part of the top finish.

"The whole extent of the rear is covered with confused piles of ruins, overgrown with trees. Near by these are fragments of walls and rooms, with a few ornaments yet remaining about them. Some of the rooms appear to have been single, and apart from all other buildings. There are also various mounds in the vicinity.

"A few rods south are the remains of a single high wall, with numerous square apertures, like pigeon-holes. Its foundation is elevated; around which the broken walls and ceilings are to be seen. The summits of the neighbouring hills are capped with gray broken walls for many miles around. I discovered no hieroglyphics or paintings of any kind; neither the extraordinary skill displayed in the ornamental carvings, as at Chi-Chen. On my route to these ruins I

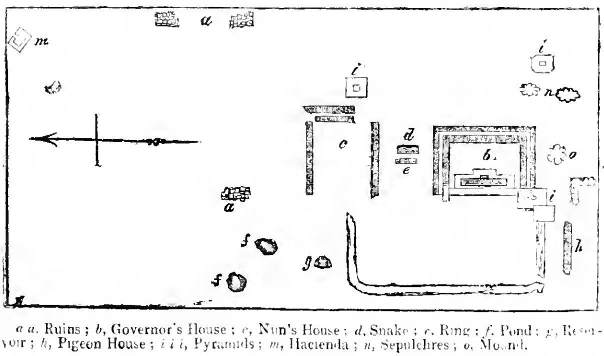
Fig. 4.—Zayi Ruins.



made digressions from the road, and found, on all sides, numerous remains of walls and ceilings; also, mounds and small pyramids, covered with the wild vegetation of the country."

Of Uxmal he gives a copious description, from which we extract the following.

Fig. 5.—Plan of the Ruins of Uxmal.



a a. Ruins; *b*, Governor's House; *c*, Nun's House; *d*, Snake; *e*, Ring; *f*, Pond; *g*, Reservoir; *h*, Pigeon House; *i i i*, Pyramids; *m*, Hacienda; *n*, Sepulchres; *o*, Mound.

"The Governor's House is a vast and splendid pile of ruins. It stands upon three ranges of terraces; the first of which is a slight projection, forming a finish. The great platform, or terrace above it, measures upwards of 500 feet long, and 115 broad. It is encompassed by a wall of fine hewn stone 30 feet high, with angles rounded, still in good preservation. In the centre of this platform, upon which trees and vegetation grow in profusion, stands a shaft of gray limestone in an inclined position, measuring twelve feet in circumference and eight in height; bearing upon its surface no marks of form or ornament by which it might be distinguished from a natural piece. Near by is a rude carving of a tiger with two heads; also, I saw excavations near them with level curbings and smoothly finished inside, which are conjectured to have been cisterns or granaries. Along the southern edge of this platform are the remains of a range of small pillars, now broken and in confusion.

"Upon the north-west corner of this platform is an edifice, which was, no doubt, from its location, connected with the Governor's House. It is the smallest of all the ruins. Its ornaments are few and plain: the most remarkable of which is a continuous line of turtles, cut from stone of about a foot square, arranged under the cornices.

"The south-west corner has connected with it two piles of loose stones, in the pyramidical form: one 80, and the other 100 feet high, the sides of the bases measuring about 200 feet. Their tops are broad platforms, over which, and down the sides, are scattered the remains of edifices, of which these pyramids were once probably the foundations. Here we found pieces of pottery, consisting of broken pieces of vases, and supposed cooking utensils.

"Upon the main terrace stands another of smaller dimensions, constituting the foundation of the Governor's House. The measurement of this terrace is 338 feet long, 32 broad, and 30 high, having a majestic flight of stone steps, though considerably broken at the centre, in front of the entrance.

"This majestic pile faces the east, is 272 feet long, 36 broad, and 24 high. The whole building is plain (unlike those of Chi-Chen) from the base to the mouldings, which run through the centre over the doorways; above which, to the top, are ornaments and sculptured work in great profusion, and of the most rich, strange, and elaborate workmanship. It is divided into double ranges of rooms, from front to rear. Two of the principal are situated in the centre, 54 feet long, 10 broad, and about 19 high, with an angular ceiling, occupying one-half of the whole. There are 14 other rooms in the front and rear; also, two rooms on each end, and one in front and rear of the two recesses, of about one-half of the average size.

"The interior of these rooms is sometimes covered with a beautiful hard finish, and at others presents a surface of uniform square blocks of smooth stone. The floors are of stone, covered with a hard composition, which, together with the stone is now much broken.

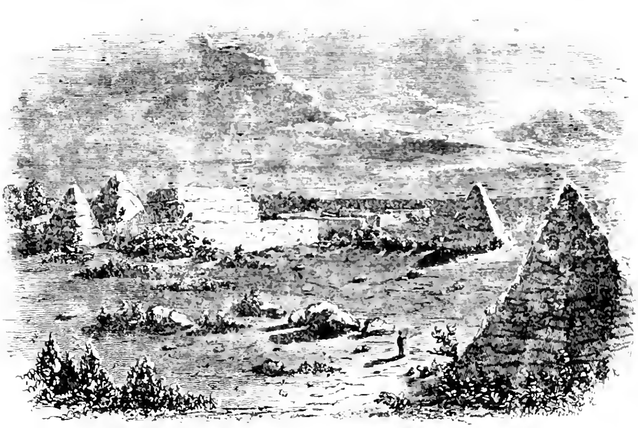
"The lintels, which are of zuporte wood, are decayed and broken, to which, in a great degree, the falling of the walls may be attributed. The inner sides of the doorways are pierced, and hooks attached, whereon doors were probably swung. There are, also, apertures in the walls, where beams rested, to support hammocks, some of which still remain, and show the marks of the cords. There were no fresco, or other painting or decorations of any kind in the interior of the building to be discerned.

"The front presents the most remarkable architectural skill to be found about the building. The walls were of the most durable kind of limestone; and upwards of three feet thick, of fine hewn stone, laid with the greatest care. There were eleven doorways besides those of the recesses. The finish of the angles, generally, was as smooth as though the material were cut with a sharp knife.

"The ornaments were composed of small square pieces of stone, shaped with infinite skill, and inserted between the mortar and stone with the greatest care and precision. About two-thirds of the ornaments are still remaining upon the façade. The most elaborate were over the centre or main entrance. These have fallen, and now are a heap of ruins at the base. One of them was a figure of a man, with a head-dress of feathers and tassels: part of which still remains, with lines of hieroglyphics underneath. The ground-work of the ornaments is chiefly composed of raised lines, running diagonally, forming diamond or lattice-work, over which are rosettes and stars; and, in bold relief, the beautiful Chinese border.

"From the centre of the building to the recess, at the northern extremity of the building, the ornaments have mostly crumbled off, and are now lying at the base in ruins; and the other parts, contiguous, seem ready to follow the example. The rear of this edifice is more plainly finished; the main part of the centre has fallen.

Fig. 9.—Uxmal Ruins.—Moonlight.



"Over the principal doorway are the remains of a female figure, in a sitting posture. The hands and legs have fallen. It has a fine head-dress of cap and tassels, and neck ornaments. The waist looks quite natural, and the whole was finely finished. On each side of this figure was hieroglyphical writing. The inner rooms of the centre of the Governor's House still show the places of excavations, made some years ago, by the curate of Ticul." * *

"A moonlight scene from the Governor's House is one of the most enchanting sights I ever witnessed. The moon had risen about half-way up from the horizon, and was now throwing its strong silver light over the whitened façade of *our house*. Castles, palaces, and falling pyramids were distinctly to be traced in the foreground. At a distance, walls and mounds, rising above the green verdure of the land, looked like a multitude of small islands in a calm summer's sea. All was quiet but the chirp of the cricket, or the occasional scream of some night-bird of the wood. It was a scene of natural beauty such as I never have seen realized upon canvass of the artist, or even in the pages of poetry."

Mr. Norman's work contains a sketch of the Maya language, and the latter portion is devoted to speculations on the population of America, and on the history of the remarkable antiquities to be found in different parts of the continent. The Maya language resembles the Chole, a language of Mexico, and is of very remarkable structure, the grammatical forms very much resembling the English, except that suffixes are used. A striking point is the use of auxiliaries with the verbs, a general indication of the descent of a language from one of richer forms. The assumption of what we may call the auxiliary state, is a remarkable and inexplicable philological phenomenon of which the instances are very frequent: and we may mention Anglo-Saxon and English, Hellenic-Greek and Romaic, Persian and modern Persian, Sanskrit and Bengalee. We have neither had time nor opportunity to compare the Maya language with many of the American continent, but we have with the Aymara (Peruvian) some of the Brazilian dialects, the Paraguay Guarani and Abipone and the Californian, and the result is no apparent resemblance with any of the languages but the Aymara. The Brazilian and Guarani are as closely allied as Spanish and Portuguese, but seem to have no points of resemblance with the others, and use affixes instead of suffixes. The Aymara, it is to be observed, is one very extensively spread in Peru, and is spoken by the Canchis, Castas, Collas, Collaguas, Lupacas, Pacases, Caranças, Charcas, and others, being the native language of the Lupacas. This language has been a good deal cultivated by the missionaries, as the Maya has been, and a grammar of Aymara was published at Rome as early as 1603, the first Maya grammar appearing in 15[illegible]. The following words seem to show a resemblance between the two languages.

	Maya.	*Aymara.*
Father	hachyum	Auquihana
Mother	hachnaa	tayca
Man	uinic	haquenaca

In construction there is also a considerable resemblance, the pronouns being suffixed to the other words. The following is an example of pronouns in the two languages.

	Maya.	*Aymara.*
My	in	na, ana, nahasa
Ours	ca	cha, cass
His	u	ru
Theirs	au	ana

The general resemblance between the Aymara and the Maya appears in actual observation to be as close as that of two families of the Indo-European languages, but does not extend to general words, only to some of the simple words, and to construction.

Into Mr. Norman's speculations we cannot enter, but we cannot resist observing that the general evidence seems to bear upon the common origin of the civilized races of America, and their relationship to the civilized races of the old world. When we trace the Indo-European languages up to their common stock, we find in the Sanskrit, Zend and Persian types, although many points of resemblance, many points of diversity, and perhaps no greater difference exists between the Japhetic, Semitic, and Hamitic languages, or whatever the classification may ultimately be determined to be. It certainly is the case that although there is a distinct character of the Semitic [1] and Indo-European languages, that points of identity are to be discovered, while among the scattered people of the Pacific ocean, many relics of language are to be found, which may have a relationship with those two great divisions. [2] There is nothing, therefore, to countenance any departure iu that respect from the testimony of the sacred records as to the common origin of the several human races. Supposing the American civilized races to have migrated from Iranistan, their route might lay through southern Siberia (in which ancient and extensive monuments are to be found), across the Pacific to the Columbia, by the course of that river to the valley of the Mississipi, thence through Mexico, to the western coast of South America. The circumstance of a race not occupying the whole of a country, is frequently to be found in the migrations of the Indo-European nations. Thus it is questionable if Scandinavia and Ireland were ever occupied by what Mr. Winning calls the Perso-European races, who pushed out the Medo-European races. A subsequent Mongol invasion of the American continent, taking a different route, might have supplanted the civilized population, and extended its settlements in the same way that is familiar to us in the history of Europe. But we must leave such speculations, and wait for the researches and labours of others to reveal that fossil history of America, which will yet be digged from its monuments, and collected from among the tribes of its children, secluded in mountain fastnesses.

Martin Chuzzlewit. By Boz. London: 1843.

It must be confessed that we seem to go altogether out of our way in bestowing any notice on a work of this kind; still, as Mr. Dickens treats the architectural profession rather cavalierly in this new production of his, we feel ourselves called upon to be equally free with him, and must tell him, that, as far as they have yet been shown, both his Mr. Pecksniff and his Tom Pinch are errant caricatures—not only over-drawn, but ill-drawn—fantastic creatures of one who seems to mistake sheer extravagance for imagination. It now looks as if Mr. Dickens had been quite spoilt by success, and accordingly fancies that whatever he writes will be sure to take with the pubiic. So far, he may not be very much in the wrong, for we believe that had "Chuzzlewit" been given to the world without his name, it would have been pronounced "sad stuff." What should be character is only coarse caricature, and is laid on, not with the pencil of a master, but with a *trowel*. Mr. Pecksniff might do for a "Gin-Palace" architect, but for nothing better; and even then his barefaced hypocrisy, as blundering too, as it is barefaced, is perfectly gratuitous, and by no means a professional trait. We may therefore suppose, that such as it is, that character is intended as an individual portrait, the original of which we are quite unacquainted with. At all events, it is a highly disagreeable and absurd one; and wholly destitute of probability. It might be rendered a vehicle for wholesome satire, but not, we fear, by Mr. Dickens, for to say the truth, he appears to know very little either of architecture, or the profession. In fact, he evidently *shirks* the former, otherwise he would have shown up the absurdities of Mr. Pecksniff's own designs, and would have let the public see what arrant humbug and quackery will impose upon it. Humbug, however, is by no means confined to the architectural profession: at the present day there is more than enough of it, on the part of those *critics*, who would fain persuade us that we have got another Henry Fielding in Charles Dickens; which we shall believe when we believe that Tom Moncrieff is a second William Shakspere.—After all, we may be mistaken in one very essential point,—namely, the authorship of the work: inasmuch as it professes not to be written, but merely *edited*, by Boz. Consequently he does not give it to the world as his own, and has probably merely been employed to lick into shape some other person's literary cub.

[1] We may note that we have observed great resemblance between the affixes and suffixes of the Hebrew and Arabic and the Magyar, and in the pronouns generally.

[2] It is curious to observe the wide spread of the roots mira (Sanscrit), sea or water, and ship or skiff,—words perhaps which boast of the most extensive diffusion; and admitting the seat of the human race to be in Iranistan, easily to be accounted for by the neighbourhood of the Euphrates and the Indus, the Persian Gulph, the Arabian and Caspian seas.

Ancient and Modern Architecture. By M. Jules Gailhabaud. London: Firmin Didot, 1842. Parts 4, 5, 6, and 7.

The interest of this work continues unabated. We find in the numbers before us, the Tower of the Giants at Gozo, Temple of Segesta, St. Vital at Ravenna, the Cathedral of Freyburg, the Certosa at Paira, the Mosques of Cordova, and Ebu Touloun at Cairo, and a Gallery in the Church of the Madeleine at Troyes. The two plates of St. Vital and its details give as good an idea of that remarkable monument as could be desired, and also another remarkable monument of very remote antiquity, the Tower of the Giants, is extensively illustrated. The designs seem, indeed, to be executed with that care which is requisite to give them value, as a work of reference.

The Topographer and Genealogist. Part I. London: J. B. Nichols.

This is a quarterly work, which takes up a good position in a field where much service is to be done. In the first article on the Earls of Lincoln, we recognize a spirit of critical research, which promises to do much good in the weed-abounding field of genealogy; but we should have liked also a more comprehensive grasp of the historical bearings of the subject. The *catalogues raisonnées* of brasses, monuments, and new antiquarian publications, will prove invaluable to the amateur and student, and makes stores of information readily available, which now require unnecessary labour to reach. If this work can but keep pace with the mass of scattered information constantly springing up on the subjects of its research, and present regular digests of them, as digests of cases are supplied to the legal profession, antiquarian and topographical studies will be very much advanced. We may notice a slight clerical error, by some mistake. Mr. Akerman's valuable Glossary of the Wiltshire Dialect has crept under the head of works relating to Yorkshire.

Examples of Encaustic Tiles. Part III. London: J. B. Nichols.

This number contains some examples of heraldic tiles, which perfectly show the applicability of this material for such kind of decoration. It also illustrates a series of wall tiles from Malvern, and the curious tile from Worcestershire, bearing the following inscription here slightly modernized.

"Think, man, thy life may not aye endure—
That thou dost thyself, of that thou art sure,
But that thou keepest, unto thy *factor's* cure.[1]
And ever it avail thee, it is but adventure.[2]

Mr. Nash reads *executor*, but we should suggest *factor* or *faicteur*, an agent, by which the applicability of the text is equally maintained, and its language better preserved.

BADEN-BADEN.

The new *Trinkhalle*, or Pump-room, by the architect Hubsch, at Baden, is spoken of in terms of very high commendation by a writer in a German periodical. "I consider this building," he says, "to be one of the happiest specimens of architecture that have been produced in our times. Delightfully situated, the structure itself is beautiful in its form and proportions, and unaffectedly expressive in character,—significant in design, and preserving a tasteful medium between unmeaning decoration on the one hand, and bare and dry scantiness of it on the other." The building is raised on a boldly rusticated substructure, and consists of seventeen open arcades, whose flattened arches spring from columns, which last are uot according to any particular order, except that their capitals, being foliaged, partake of the Corinthian character; but the columns themselves are of

[1] Care. [2] Chance.

shorter proportions, and the angles of the abacus are cut off so much as to render that member octagonal. The centre consists of five arches, resting on two antæ and four columns, with steps leading up to it, and is crowned by a pediment with a bas-relief by Reich, a young sculptor now rising into celebrity. The merits of the design must, however, be taken entirely upon trust, for there is very little amounting to description in what Ernst Förster says of it. Some particulars that might easily have been stated are passed over altogether, notwithstanding that, for want of them, it is impossible to form any distinct idea of the structure. There is, for instance, not a single dimension given by which we might even guess at its size: nor is it even so much as said whether it is an edifice of any magnitude. We are again quite at a loss to understand whether the "seventeen arches" spoken of belong only to the principal elevation, or not. The "description," in short, is of that kind which, though it may be clear enough to those who have seen either the building itself, or drawings of it, is unintelligible without such additional information,—a very common, but also a particularly provoking, fault.

DREDGING AND DREDGING MACHINES.

[The following communication describes a practice called *radius cutting*, which has been recently introduced into several large dredging operations. In this new process a lateral sweep, or circular motion, is given to the ladder, or bucket frame, which swings upon its upper extremity as a centre, and in its action imitates that of a scythe in mowing,—with this difference, that the scythe only cuts from right to left, whereas the buckets cut both backwards and forwards, which is the meaning of our correspondent when he says the machine cuts in both traverses. According to the old system of working, which our correspondent styles *trench cutting*, the bucket frame has only a vertical motion, the effect of raising or lowering its inferior extremity by means of ropes and sheaves fixed at the bows of the vessel. The machine could only cut right forward in straight lines, and had to be hove up to its work or dropped down from it when the buckets had done their work in the axis of the frame. Our correspondent contends that the zigzag motion from one cutting position—that is, from one trench to the other—is inconvenient, and occasions a loss of power; that the buckets cutting in trenches are very liable to cut in holes where the bottom is already sufficiently deep; and that after the dredging has been executed in parallel lines, there are still ridges left between the trenches which must be worked off by a repetition of the process. At present we are not able to see clearly how the two latter of these objections are obviated by the new system of radius cutting. However, we insert the letter of our correspondent in full, and shall be happy to receive further information as to the working of this system.—Ed.]

Sir—Having twice had to make out plans and specifications of new dredging machines for works where I have been an assistant, I have bestowed a good deal of attention on this subject; and recent accidents to masonry where modes of cutting other than dredging have been adopted, have induced me to send you the following remarks on the new system of "Radius cutting," which has been found so successful on one of the largest navigation improvements at present going on.

In the ordinary method of "trench" cutting, the power applied to lead the machine ahead into the cutting, has also to resist the reaction of the buckets: so that in the Dublin machines it was thought worth while to take the power from the engine. In the Clyde boats this process requires a great expense of manual labour, but Mr. Bald has taken the power from the engine in the newest machine[1] (No. 5).

Now, in radius cutting, the chain from the bow of the machine is not wound up while it is cutting, but is only shortened at each return of the machine, which may be described as swinging on that chain just like the "bob" on a pendulum: the machine being led laterally to the cutting by the *side chains*. These side chains are comparatively easy to work, as the reaction of the buckets is mostly against the radius chain.

There is no more difficulty attending the use of these lateral chains in a harbour, or narrow navigation, than in "trench" cutting, where corresponding chains, or "guys," are required to keep the machine in line, and these are necessarily used on both sides at once; whereas these lateral chains are only tightened on one side,—namely, that on which the machine may happen to be traversing; and where it is required to lower them, to allow vessels to pass, they have only to be tightened up till the buckets fill again.

In the old system of working the boat *ahead*, it has to stop when it has cut a trench, come back over the same ground, and be set again to commence cutting another trench: and after the requisite breadth is traversed, the machine must again work over the same breadth, in the same zigzag manner, to cut the "ridges" which were left between the "trenches." This is the most clumsy and unprofitable part of the system, as these ridges yield before the buckets when soft, and stand when hard, causing a continual raising and lowering of the "ladder." Any engineer may satisfy himself of this, by standing to see the soundings at the "well," which are so irregular that half the full work is not performed: and there is no doubt of the immense loss, by the machine cutting in what is termed "holes."

All these evils are greatly reduced by working with a radius chain. The machine cuts in both traverses, and carries the work clean before it. The surface of the bank can be pared to any level, the machine passing over the hollows and cutting only the heights, and so never wasting time by dredging in holes.

There is no loss from taking the machine rapidly over the ground, when such might be required to keep the buckets full: but in the old system there would be a great loss in doing so, and paring only to a certain extent at each run,—for the backing of the machine is a dead loss of time. Yet though this loss is obvious, there might be a greater, from endeavouring to reduce it by keeping the buckets full the whole length of the trench, for then they might get into holes; and if a machine continue to lift quick stuff from a hole which may happen to be near a hard part of the bank, it can do little good, as the hole, if very quick, fills up of itself, or may soon be expected to collect alluvial matter.

Although it may be true, that, to cut or trench a bank in the proper current, will, by changing the currents and eddies, remove it by a natural process; yet, as this is a point so difficult to hit upon, it is generally allowed, that, to get large stones and rocks taken up, and to cut the surface fair, is the surest way of reducing a bank, and of leaving it in the condition least liable to "silt up."

It is with these views of the advantages to be derived from the judicious application of machines, that the preceding mode is brought under the consideration of your readers.

There have been great improvements made in the machinery by the practical engineer; but the civil engineer has not made any corresponding advancement in the working of the machine, although it is his right hand instrument. By attention to the working of the machine, much time and expense may be saved, which no improvement in mere construction of the machinery could ever effect. Dredging machines seem just to be put into the hands of their captains and engine-keepers, to make the best of them. And it cannot be doubted that the performance of these machines might be greatly increased by improved application; indeed, the improvements here described go far to prove this, as they effect a saving of at least one-fourth of the power. When men of science bestow due attention on the subject, farther advancement may yet be made, and the dredging machine be found not only by far the most safe and expeditious, but also the cheapest mode of cutting.

The difference of construction in the machine for working on the radius principle is very little, and need only be made at the lower end of the bucket ladder. As the machine is led side-ways to the stuff, the lower "tumbler" has no flanges, as in the ordinary tumbler, on which they are necessary to assist in keeping the buckets from swerving as they are pressed forward; but instead of the flanges there are "snugs" on the tumbler between the chains to keep them on. It would be useless to notice other parts of the construction in this paper, as that is the characteristic difference. The four crab winches usually erected on the deck of a machine serve with a snatch-block to wind the traverse chains.

30, *Hope Street, Glasgow*, W. C., C.E.
21st March, 1843.

[1] No dredging machine is complete unless the work of heaving the vessel ahead be performed by the engine. It is one of the most obvious applications of the steam power by which the machine is worked, and we believe some of the earliest engines—for instance, those on the Caledonian Canal—were so contrived, as to be hove forward by the engine when required.—Ed.

Bell Rock Lighthouse.—The monthly return from this establishment for February takes notice of a heavy sea upon the rock, from the north-east, on the 14th and three following days, when the spray rose from 70 to 80 feet on the lighthouse tower. On each of these days, says the return, "we felt the building tremble but very little." Various of the travellers or boulder stones upon the rock have been shifted from "Arniston and Ulbster" ledges to the west end of "Hope's" Wharf. The boulders connected with the "Royal Burghs" have also been tossed about; one of these measures nine feet in length.—*Caledonian Mercury*.

ABERYSTWYTH HARBOUR.

Sir—In perusing "Blackford and Imray's Charts and Sailing Directions for St. George's Channel, 2nd ed." lately published, at p. 40 I find an account of this harbour as follows:—"Aberystwyth Harbour is a narrow creek, and not fit for vessels that draw above 9 or 10 feet water, and these must have spring tides to go over the bar." From the following account it will be seen what alterations have taken place through engineering skill, which has completely set aside the above description.

The Harbour of Aberystwyth is situated in the bottom of the Bay of Cardigan, terminated by Bardsey Island on the North, and Strumble Head on the South, and lies about 5 leagues E.N.E. from New Quay, but more immediately between two points of land, the Castle Hill on the North, and Alltwen on the South. Between these two points of land, the Rivers Rhydiol and Ystwyth empty themselves into the sea. Aberystwyth Harbour may be distinguished at some leagues distance by Pen Dinas Hill, which rises steep on the south end, also by the ruinous castle near the town.

The sea coast here about is nearly N.N.E. and S.S.W. by compass bearings; the prevalent winds from the W., and more especially from the W.S.W. produce the heaviest swells; for in that direction the Aberystwyth coast lies exposed to the fury of the Western Ocean.

The Harbour, in its original state, was probably only the mouth of a mountain river, the Rhydiol, which, after a course of about 20 miles through a slate stone soil, falls into the sea. The Rhydiol, like other mountain streams, is subject to sudden and violent floods, or freshes, during rainy seasons, and a great quantity of slate, gravel, and other matter is brought down the river by the effect of these freshes. The foregoing observations equally apply to the River Ystwyth. The Ystwyth having united its waters with the Rhydiol at the entrance of the Harbour, these two rivers maintain one common outfall, through the beach into the sea. The slate gravel brought down the rivers, and the beach that was brought from the southward, accumulated, and being thrown up by the action of the sea, a *bank* or *bar* was formed at low water. This bar offered a constant obstruction to vessels, in their ingress and egress, and often caused great destruction of life and property.

Now to show what engineering has done. In the year 1838, the trustees commenced a substantial new stone pier on the south side of the entrance of the harbour, to protect the harbour from the western gales, and to prevent the beach from accumulating and forming a bar. This pier is now (1843) extended from the beach 260 yards in the direction of SSE and NNW, and as far as is completed, has fully answered their expectation. In the first place, it has stopped the progress of the beach, and deposited the same at the back of the pier. Secondly, it has guided the rivers into a proper channel, by which it has caused a deeper channel to be formed, and removed the bar. Thirdly, instead of 9 or 10 feet water at spring tides, it has now obtained that height or more at the neap tides, and an average of 16 feet at spring tides. Lastly, it has removed that danger to vessels and mariners arriving or sailing or having to wait in the bay during the neap tides, for water to enter the harbour. The portion of the river Rhydiol and the harbour at high water, occupy an area of about 20 acres. On the pier is erected a powerful capstan, supplied with ropes, and a store house; and about 400 yards to seaward off the end of the pier, are moored two large transporting buoys, lying in 4½ fathoms low water spring tides, for vessels to moor to or warp from, and every facility is rendered vessels making or leaving this port, by signals and lights at tide times; it is now considered by all mariners that visit this port to be the best tidal harbour in the principality, when, but a few years since, it was the worst.

Vessels visiting this port can be supplied with every accommodation for repairing, &c., there being two ship-building departments, a rope walk, and sail makers, also bar and block warehouses. The markets are well supplied, and sufficient stores can be obtained.

An Old Subscriber.

Aberystwyth, March 1*st*, 1843.

STEAM POWER.

Sir—The detailed table of the values of the different degrees of expansion in the engines of the *Great Britain*, which appeared in the March number of this *Journal*, afforded me much pleasure, since they will tend to produce a conviction of the advantages in the minds of owners of steam boats, who might disregard the form in which it has been already advocated in your pages.

In consequence of an inadvertent change of my expressions from "a cubic foot of water *expended as steam*, is equivalent to one horse power per hour," to "the evaporation of a cubic foot of water is equal to one horse power," you appear to have overlooked the limits I intended to apply to the assertion. The words in italics, which had been used in a few lines above as "*expended as steam in the cylinder*," were inserted to exclude the power due to expansive action, as well as the waste, 1st, in blowing off, 2nd, at the safety valve, 3rd, clearance steam, and 4th, cooling. I happened to roughly estimate these losses at 1 lb. of water for an expenditure of 7 lb. of water as "dense steam" doing work in the cylinder, while the communication with the boiler remained open, making the boiler evaporation identical with your assumption: and I feel assured you will grant me permission to refer to this charge of inaccuracy, and to the standard of horse power assumed in my remarks on nominal horse power in the *Nautical Magazine*.

I merely followed Tredgold in the assumption that steam of atmospheric strength will produce 3,600,000 lb. pressure one foot high, and consequently maintain during one hour, a gross power on the piston of 60,000 lb. one foot high; and I apprehend this assertion is equally true, with a slight increase for higher steam, and a slight decrease for steam below the atmosphere for the "*dense steam*" not worked expansively.

As a secondary assertion I added "this gross power is capable of producing 33,000 lb. on the connecting rod," and perhaps in the best engines from 40 to 50 per cent. more, still it is not competent to produce an excess of 75 per cent., and much less an excess of cent. per cent. as due to 14 lb. net pressure, which amounts to 66,000 lb. per minute.

This standard of 60,000 lb. gross pressure I had understood has been occasionally used, or been recommended to be used, by civil engineers in contracts, to prevent disputes with engine makers respecting the excess of power above nominal horse power to be supplied, and it seems a fair mean. Moreover, it meets the difficulties arising from higher steam, and the reduction of power due to expansion, and it is equally applicable to non-condensing engines (the estimate of horse power of these engines seems somewhat undefined).

The employment of an indicator, the value of which you have adverted to, is obviously required in estimates of the above nature; and though well adapted as a standard of comparative power and coal consumption, yet nominal horse power might still be used as a measure of the size of the engine: which seems a good commercial unit, of the same value as the diameter in inches, of the cylinder used in Cornwall, where the loads vary from 5 lb. to 16 lb. per square inch, and the strokes from 2 to 11 per minute in large engines.

Accustomed to refer to the "work performed" or duty, I concur entirely in the appeal to the "work to be done" by the engines of the *Great Britain*, especially as I anticipate the most favourable results from the mode in which the designers of the *Great Britain* have availed themselves of the condition that their capacities increase in a faster ratio than the areas of the midship sections of vessels.

I have the honour to remain, Sir,

March 10*th*. Your's, obediently,

John S. Enys.

INSTITUTION OF CIVIL ENGINEERS.

Jan. 10.—The President in the Chair.

The business of the meeting was commenced by reading an abstract of Mr. Davison's paper (No. 539) describing the mode adopted for sinking a well at Messrs. Truman, Hanbury, Buxton, and Co.'s Brewery, which was published in the minutes of proceedings of session 1842, p. 192, and the following observations were made.

Mr. Braithwaite described the difference between the method employed in sinking the well for Messrs. Truman and Co., and that for Messrs. Reid and Co. In the former the bore was small, and would therefore only produce as much water as was procured from the veins through which it passed vertically, while the latter, by its larger diameter, permitted lateral galleries to be driven in the direction of the fissures in the chalk: thus forming feeders for the well, and at the same time capacious reservoirs wherein the water accumulated when the pumps were not at work.

He attributed the comparative failure at Messrs. Truman's to errors in the mode of sinking: the length of the cylinders which had been attempted to be forced down was too great, and the lateral pressure had prevented them from reaching the chalk, so that when the pumps were set to work an undue quantity of sand was drawn up with the water, causing a cavity behind the brick-work, which at length fell in. The water having been pumped out to a lower level than was proper, the equilibrium between the water and the sand around the cylinder had been disturbed, and the "blow" of sand had ensued.

The New River Company had been advised to sink a well of sufficient diameter to enable them to excavate lateral galleries, but they had sunk their well in the Hampstead Road, of a small diameter, as described in the paper by Mr. R. W. Mylne, published in the third volume of the transactions of the Institution;[1] and although fissures had fortunately been traversed, which gave an ample supply of water, many of the difficulties encountered would, he contended, have been avoided by adopting the larger diameter, and sinking the cylinders into the chalk, before the pumping was commenced.

The supply of water at Messrs. Reid's well had been sensibly affected by the recent proceedings at the Hampstead Road well, which was now being constantly pumped in order to sink it deeper.

Mr. Davison explained that a bore of small diameter had been adopted, because it was calculated that a supply of water, sufficient for the wants of the brewery, would have been obtained by it. The excavation to within five feet of the chalk was suggested by the sudden dropping of the cylinder. He believed that when (contrary to his express instructions) the level of the water was reduced by pumping to below a given point, the sand from beneath the oyster-bed rushed in to restore the equilibrium within the cylinder, and thus caused the difficulties which he had to contend with.

During the last year the pumps had been at work 1616 hours, in which time 300,000 barrels, or 50,000 tons, of water had been drawn from the well.

Mr. Farey believed that the casualties in well sinking, generally arose from the sources which had been mentioned. Mr. Woolf encountered them when sinking the well at Messrs. Meux' (now Messrs. Reid's) brewery. The pumping up of sand with the water was there carried to such an extent as to cause an accumulation of sediment two feet deep in the liquor back, in 14 days, and ultimately the new well broke into the old one adjoining it.

Mr. Braithwaite explained, that, in the year 1814, the well at Messrs. Meux was pumped "to clear the spring," which caused a cavity of nearly 40 feet deep from the sides of the well, and endangered the stability of the buildings around. Piles were therefore driven to support the upper ground, and upon them the brick steining was carried up. If the cylinders had in the first instance been carried down to the chalk, before the pumping had commenced, this accident would not have occurred.

Mr. Vignoles remarked that the same question, as to the relative merits of boring or sinking, had been discussed at Liverpool, for wells in the red sandstone, and in practice it had universally been found that, by the latter system, the best supply of water had been procured, particularly when side drifts had been made.

Mr. Mylne said that the works at the well in the Hampstead Road, which had been repeatedly stopped from accident, were now resumed as an experiment; the quantity of water obtained was more than could be drawn by a pump 12 inches diameter, 6 feet stroke, making 10 strokes per minute (= 294 gallons per minute). The spring was struck at about 231 feet below the surface of the ground, and when the engine was regularly at work, the water generally stood at within 20 feet from the bottom of the well. He coincided in the opinion of the advantage of a well of large diameter over one of small bore, as it permitted side excavations to be made in search of water. This plan had been pursued with success at Brighton.

Mr. Taylor observed that another of the advantages of the large diameter was, that the proceedings could be watched, and accidents could be more readily remedied; the opinion of all practical miners was, that the large diameter was cheaper, as well as better, than the small bore.

Mr. Clark promised an account and drawings of a well now sinking by him at the Royal Mint. The advantages of a large diameter were manifest to all practical men, particularly when the augur or "miser" was used, as it enabled the operation to be continued without pumping; the cylinder, in lengths of not more than 30 feet each, followed the "miser" down regularly, and as soon as they reached the chalk, the operation was considered safe; and as the "miser" did not excavate more than was due to the area of the cylinder, the equilibrium between the water within and the sand without the cylinder was never disturbed. In a well sunk by him at Messrs. Watney's distillery, the cylinders were 11 feet diameter; the "miser" used was 5 feet diameter, and was turned by twelve men at a time.

Mr. Braithwaite concurred in the advantages of using the "miser;" he invariably employed it, and generally with success.

Mr. Farey believed that the augur or "miser" was first used in this country by the late Mr. Vulliamy,[2] of Pall Mall, for sinking an Artesian well, into which there was an irruption or blow of sand, the effect of which was only overcome by this instrument.

"*An Experimental Inquiry as to the Co-efficient of Labouring Force in Overshot Water-wheels, whose diameter is equal to, or exceeds, the total descent due to the fall; and of Water-wheels moving in circular Channels.*" By Robert Mallett, M. Inst. C. E.

This paper is partly mathematical, and partly experimental. The investigation which it details, the results of which are given in ten tables of experiments, had in view principally to obtain the definite solution of the following questions.

1st. With a given height of fall and head of water, or in other words, a given descent and depth of water in the pentrough, will any diameter of wheel greater than that of the fall give an increase of labouring force (*i.e.* a better effect than the latter), or will a loss of labouring force result by so increasing the diameter?

2nd. When the head of water is necessarily variable, under what conditions will an advantage be obtained by the use of the larger wheel, and what will be the maximum advantage?

3rd. Is any increase of labouring force obtained, by causing the loaded arc of an overshot wheel to revolve in a closely fitting circular race, or conduit? and if so, what is the amount of advantage, and what the conditions for maximum effect?

The author briefly touches upon the accepted theory of water wheels, the experimental researches of Smeaton, and the recent improvements in theory, due to the analytic investigations of German and French engineers.

Smeaton, in his paper on water wheels, read to the Royal Society in May, 1759, and Dr. Robison, in his treatise on water wheels, lay down as a fixed principle, that no advantage can be obtained by making the diameter of an overshot wheel greater than that of the total descent, minus so much as is requisite to give the water, on reaching the wheel, its proper velocity.

The author, however, contends that while the reasoning of the latter is inconclusive, there are some circumstances which are necessarily in favour of the larger wheel, and that conditions may occur in practice, in which it is desirable to use the larger wheel, even at some sacrifice of power; and that hence it is important to ascertain its co-efficient of labouring force, as compared with that of the size assigned by Smeaton for maximum effect.

The author states, first, the general proposition, "that the labouring force ("travail" of French writers), or "mechanical power" of Smeaton, of any machine for transferring the motive power of water "is equal to that of the whole moving power employed—minus the half of the *vis viva* lost by the water on entering the machine, and minus the half of the *vis viva* due to the velocity of the water on quitting it." He deduces from the theory, the following results, coinciding with the conclusions obtained by experiment.

1st. If the portion of the total descent passed through by the water before it reaches the wheel be given, the velocity of the circumference should be one-half that due to this height.

2nd. If the velocity of the circumference be given, the water must descend through such a fraction of the whole fall before reaching the wheel, as will generate the above velocity.

3rd. The maximum of labouring force is greater, as the velocity of the wheel is less; and its limit theoretically approaches that due to the whole fall.

General equations are given, expressing the amount of labouring force in all the conditions considered, and their maxima.

One of the principal advantages of using an overshot wheel greater in diameter than the height of the fall, is the power thus afforded, of rendering available any additional head of water occurring at intervals, from freshes or other causes, by admitting the water upon the wheel at higher levels.

The first course of experiments is dedicated to the determination of the comparative value of two water wheels, one of whose diameter is equal to the whole fall, and the other to the head and fall, or to the total descent; by the head, being in every case understood, the efficient head, or that due to the real velocity of efflux at the shuttle, as determined according to Smeaton's mode of experimenting.

The apparatus employed in this research consisted of two accurately made models of overshot wheels, with curved buckets. These were made of tin plate, the arms being of brass, and the axles of cast iron. Special contrivances were adopted to measure the weight of water which passed through either wheel during each experiment, to preserve the head of water strictly constant, and to determine the number of revolutions, and the speed of the wheels.

One wheel was 25·5 inches diameter, the other, 33 inches diameter. The value of the labouring force was determined directly, by the elevation of known weights to a height, by a silken cord over a pulley; the altitude being read off on a fixed rule placed vertically against a lofty chimney; and in other experiments, relatively by the speed of rotation given to a regulating fly or vane. The depth of the efficient head was 6 inches in all cases.

The weight of water passed through either wheel in one experiment, was always 1000 pounds avoirdupoise.

All the principal results given in the tables accompanying the paper, are the average of five good experiments; from the large scale upon which these were conducted, the accurate construction of the apparatus, and the care bestowed upon the research, which was undertaken with reference to an actual case in the author's professional practice, he is disposed to give much confidence to the results.

The weight of water contained in the loaded arc of each wheel is accurately ascertained, and in the tables which accompany the paper, the results of the several experiments are given at length.

The velocity of the wheels, under different circumstances, is carefully noted and discussed with respect to the maximum force.

The author next ascertains the value of the circular conduits, and states that generally, in round numbers, there is an economy of labouring force, amounting to from 8 to 11 per cent. of the power of the fall, obtained by the use of a conduit to retain the water in the lower part of the buckets of

---

[1] Trans. Inst. C. E., vol. iii. p. 229.

[2] Vide *Nicholson's Journal of Philosophy*, vol. ii. p. 266,—"An Account of the means employed to obtain an Overflowing Well at Norland House in 1794," by Benjamin Vulliamy.

an overshot wheel, whose diameter is equal to the fall. The velocity of a water wheel working thus, may vary through a larger range without a material loss of power, and a steady motion is continued to a lower velocity than when it is working in a free race.

The author finally arrives at the following general practical conclusions:—

1st. When the depth of water in the reservoir is invariable, the diameter of the water-wheel should never be greater than the entire height of the fall, less, so much of it as may be requisite to give the water a proper velocity on entering the buckets.

2nd. When the depth of water in the reservoir varies considerably and unavoidably in depth, an advantage may be obtained by applying a larger wheel, dependent upon the extent of fluctuation and ratio in time, that the water is at its highest and lowest levels during a given prolonged period; if this be a ratio of equality in time, there will be no advantage; and hence, in practice, the cases will be rare when any advantage will obtain by the use of an overshot wheel, greater in diameter than the height of fall—minus, the head due to the required velocity of the water reaching the wheel.

3rd. If the level of the water in the reservoir never fall below the mean depth of the reservoir, when at the highest and lowest, and the average depth be between an eighth and a tenth of the height of the fall, then the average labouring force of the large wheel will be greater than that of the small one; and it will of course retain its increased advantage at periods of increased depth of the reservoir.

Dr. Robison's views, therefore, upon this branch of the subject, should, he contends, receive a limitation.

A positive advantage is obtained by the use of the conduit varying with the conditions of the wheel and fall, of nearly 11 per cent. of the total power.

The value increases with the wheel's velocity up to 4½ feet per second, or to 6 feet per second, in large wheels. Hence, he argues, that it is practicable to increase the efficiency of the best overshot wheels, as now usually made, at least 10 per cent. by this application. The only objections urged against the use of the conduit are of a practical character, relating to the difficulty of making it fit close, of repair, &c.; but however these may have applied to the rude workmanship of the older wooden wheels, with wood or stone conduits, they are unimportant, as referring to modern water-wheels made of iron. The conduits may be also made of cast-iron, provided with adjusting screws, and hence of being always kept fitting, readily repaired, and capable of being withdrawn from the circumference of the wheel in time of frost, &c.

The paper is illustrated by a drawing, showing the elevation and partial sections of the experimental apparatus, and a diagram showing the full size of the loaded arc of each model.

Mr. Farey observed, that the result arrived at by the experiments, appeared to correspond nearly with those recorded by Smeaton, who had experimented upon, and used practically both kinds of wheels. The buckets of the model wheels used in the experiments did not appear to be of the best form, and they were entirely filled with water; hence an apparent advantage had been obtained, by the use of the circular conduit to retain the water in the buckets. But that would not be realized in practice, for as the form of the bucket regulated the point at which the water quitted it, and it was the practice of the modern millwrights to make the wheels very broad, in order that the buckets should not be filled to more than one-third of their depth, the circular conduits became less useful, and in fact were now seldom used. Smeaton's practice was, to entirely fill the buckets with water, but he never adhered to the slow velocity of revolution which he recommended theoretically in his paper to the Royal Society.

Mr. Fairbairn had adopted broad wheels with an improved form of bucket, partially filled, and had obtained a more regular motion, particularly at high velocities.

Mr. Farey promised to present to the Institution, a copy of the method of calculation adopted by Smeaton for water-wheels.

Mr. Taylor corroborated Mr. Farey's statement of the advantage of using broad wheels, with the buckets of a fine pitch and partially filled; circular conduits then became unnecessary: this was practised among the millwrights in North Wales with eminent success, and a velocity of six feet per second was given to the wheel.

Mr. Homersham believed that in Smeaton's latter works he increased the velocity of his wheels to six feet per second.

Mr. Rennie gave great credit to the author for the ingenuity of the apparatus with which the experiments were tried, and for the clearness of the tabulated results; but owing to the necessary limited size of the model wheels, he feared the results could not be relied upon for application in practice to large wheels. The experiments of Borda, Bossut, Smeaton, Banks and others, were all liable to the same objection.

The best modern experiments are those by the Franklin Institute, by Poncelet, and by Morin.

The result of these might be taken thus:

Undershot wheels, the ratio of	power to effect varied from				0·27 to 0·30
Breast wheels	,,	,,	,,	,,	0·45 to 0·50
Overshot wheels		,,	,,	,,	0·60 to 0·80
Average	,,	,,	,,	,,	0·60

The velocity of the old English water-wheels was generally about three feet per second; the American wheels four feet, and the French wheels six feet: this latter speed was now adopted by the best millwrights in England. Mr. Hughes, at Mr. Gott's factory at Leeds, and Mr. Fairbairn, had found advantage from it; the latter also had a particular contrivance for carrying off the air freely from the buckets.

It was important to regulate the thickness of the sheet of water running over the shuttle upon the wheel; four to five inches was found in practice to be the maximum depth allowed.

The object being to utilize the greatest height of fall and the greatest available quantity of water, by means of properly constructed openings and such sluice-gates as were first introduced by the late Mr. Rennie for the breast-wheels constructed by him, instead of penning up the water in a trough, it was made to flow in a sheet of regular thickness over the top of the shuttle, and by a self-regulating apparatus to adjust itself at all times to the height of the water; thus obtaining the advantage of the full height of the fall at its surface, and obviating the necessity for the apparatus proposed by Mr. Mallett.

Mr. Mallett begged to dissent from the validity of the objections which had been made to the practical value of his experiments. With respect to the form of the bucket, that used by him could not, he contended, be called a bad form, although it might be susceptible of improvement; but as the experiments were altogether comparative, it was foreign to the question whether the form was bad or good, the same having been used in both wheels.

As it was shown that a certain relation subsisted between two water wheels with the same total descent, but with different diameters, as to their co-efficient of labouring force, a proportional relation would exist with any worse or better form of bucket. The results considered as absolute measures of effect, being obtained with a form of bucket which approached nearer to the best forms now in use, than did those of Smeaton or any other experimenter, were more applicable to modern practice, and therefore he must consider his results, as not without utility.

With regard to the custom of only partially filling the buckets, it must be remarked that buckets of the best forms begin to spill their contents before arriving at the lowest point of the loaded arc; the partial filling could, therefore, only palliate the evil which the circular conduit was designed to remedy. He must, however, contend that a positive disadvantage attended the partial filling. A permanent loss of fall was produced equal to the distance between the centres of gravity of the fall, and of the empty portions of the top bucket at the moment it had passed the sluice; this distance could be but little varied by the fineness of pitch of the bucket, and depended more upon the depth of the shrouding. That there was a constant loss of labouring force by a practical diminution of the effective leverage, or a reduction in the "moment" of the loaded arc. That as the wheel revolved, the centre of gravity of the fluid contained in each bucket, as it approached the lower portion of the loaded arc, was transferred to a greater distance from the centre of motion even before the contents commenced spilling; but the angular motion of the centre of gravity of any one bucket was at first that due to its distance from the centre of motion of the wheel, or to its radius; and as the radius increased, a greater angular velocity would be acquired by the water which had changed its position on approaching the lower point of the wheel; but this increased velocity was given at the expense of the power of the wheel, and hence a partially filled bucket would, he contended, be always attended with a loss of labouring force. To the last objection, a full bucket was not liable.

From all these reasons, he felt justified in concluding, that the use of the circular conduit was more advantageous than the practice of partially filling the buckets.

With respect to the shuttle delivering the water over the top, where the head of water and the fall were constant, no advantage could be obtained by the use of a wheel greater in diameter than the total descent; it was assumed that this form of shuttle would be used in order always to deliver the water as high as possible upon the periphery of the wheel; but the question was, "If the head be variable, what should be the diameter of the wheel to secure the best effect?" The paper showed that a wheel whose diameter was equal to the total descent, when the head was a maximum, did not always give the greatest average labouring force. The question was therefore independent of the sort of shuttle used; it assumed the power of always admitting the water upon the wheel at the highest point of the total descent, and sought to establish the best relation between the diameter of the wheel and the whole descent when the head alone was variable, according to given conditions. The results of this part of the investigation, therefore, while they admitted the full value of Mr. Rennie's shuttle, went further, and pointed out the limits of its useful application.

He was fully aware of the prejudice which existed against the circular conduit, and once participated in it; but his attention had been forcibly drawn to it in his practice, and having used them very beneficially upon wheels of 40, 50, and 60 horses' power, which he had constructed for mining purposes, he wished to draw the attention of the profession to the consideration of their practical merits when adapted to good wheels.

English Marble.—A bed of variegated marble has been discovered in a limestone quarry, belonging to George Pybus, Esq., of Middleton Tyas, near Richmond, Yorkshire. A small piece has been dressed by a skilful workman; the polish is beautiful, and the marble seems likely to be brought into general use.

THE PYRAMIDS OF GIZEH.

At the Royal Institute of British Architects, on the 6th ultimo, a letter was read from Mr. Perring, containing some remarks on the great Pyramid, accompanied by a model.

"The model is on a scale of 30 ft. in the inch, and represents the pyramid in its original condition,—that is, immediately after the sarcophagus was placed therein, and before the passages were filled with stone blocks closing the entrance. From an examination of the ancient Egyptian cubit now remaining, I deduced the length to be 1·713 English feet, divided into four palms, each of seven digits. This measure, when applied to the pyramids, agrees as closely as to render its correctness certain, and I proceed to mention a few of the more obvious results in the edifice before us. The base covered a square of 448 cubits on each side, which, from a statement of Pliny, I take to have been equal to eight Egyptian jugera, or acres: and this supposition is somewhat confirmed by finding the second pyramid would then cover seven, and the third, one and three quarters of these supposed jugera, and so on with the other pyramids of Egypt. The height of the great pyramid appears to have been 280 cubits, being a proportion of height to side of base of 5 to 8; and I may here mention that several other pyramids have the same proportions. This gives the following ratio on a direct section: As half the base is to the perpendicular height, so is the apotheme, or slant height to the whole base; or for each side it may be thus stated as

Rad : Tang : : Sec : 2 Rad.

"Sir John Herschel having the angles only of the pyramids and their passages before him, gave his decided opinion that they were "not connected with any astronomical fact, and probably adopted for architectural reasons;" and the knowledge of the above proportions will I think lead to the same conclusion; for with the most solid and enduring shape possible, the builders obtained a mathematical symmetry which no other proportions could give. Although this pyramid was nearly 480 feet in perpendicular height of solid masonry, the pressure of the enormous mass is so distributed, that the lower courses have only to sustain about 25,000 lb. on the square foot, whilst the material is equal to at least 1,100,000 lb.; therefore it is evident that the main objects of the architect—viz., stability and eternal duration—were well effected. The inclination of the entrance passage of the great pyramid was regulated by a proportion of 2 to 1: that is, two feet horizontal to one foot perpendicular.

"The same mode of regulating the angles is observable in every instance; thus where inclined blocks were used to cover an apartment, a certain portion of the width of the room was taken for the rise or pitch: as in the queen's chamber, where the rise is a third of the width of the apartment, and also the angle of the air passages leading from the king's chamber to the exterior, have a rise of one perpendicular to two horizontal. From finding, in every case, that the angles were thus regulated, I have come to the conclusion that the Egyptians, at the time of the erection of these mighty monuments, possessed no knowledge of the division of the circle into degrees, but that their angles were regulated by the proportion of base to perpendicular height; in fact, the tangential measure of the angle, and not its abstract measurement. That they learned to divide the circle into degrees at a later period is highly probable, as they were celebrated for their astronomical knowledge.

"In every part of the pyramids evidences of premeditated and careful design are apparent; but my present purpose is to draw attention to the more striking points in the great pyramid only. The situation of the apartments in the pyramid appear to have been regulated as follows—

Height from base (external) to floor of passage of queen's chamber	40 cubits
From the above to floor of king's chamber, or principal apartment	40 "
From the above to top of upper chamber	40 "
From the above to apex of pyramid	160 "
Total	280 cubits

Making 280 cubits in perpendicular height, as above stated. The floor of the subterraneous apartment was also 60 cubits below the base of the pyramid."

ROYAL COMMISSION OF FINE ARTS.

Her Majesty's Commissioners hereby give notice:—

1. That the cartoons or drawings intended for competition, according to the notices published in April and July, 1842, will be exhibited in Westminster Hall, whither they are to be sent between the hours of 10 and 5 on any day, Sunday excepted, during the first week in June next, when agents will be in attendance to receive them; but no drawing will be received after Wednesday, the 7th of June.

2. Each candidate is required to put a motto or mark on the back of his drawing, and to send, together with his drawing, a sealed letter containing his name and address, and having on the outside of its cover a motto or mark similar to that on the back of the drawing. The letters belonging to the drawings to which no premium shall have been awarded will be returned unopened.

3. The title of the subject of each drawing, together with the quotation, if any, to illustrate it, must be affixed either to the back or front of the drawing.

4. Each drawing is to be sent upon, or accompanied by, a stretching-frame; but no ornamental frames in addition to the stretching-frame will be admissible.

5. The artists or their agents may attend to examine the works sent by them, and to re-stretch such drawings as shall have been detached from their stretching-frames and rolled for the convenience of carriage.

6. No drawing will be allowed to be re-touched after having been received, except to repair an injury occasioned by accident, and then only by the artist himself.

7. Every possible care will be taken of the works sent, but in case of injury or loss, the commissioners will not be responsible.

8. All the drawings will be exhibited, and catalogues will be published.

9. The names of the judges appointed to award the premiums will be made known.

By command of the Commissioners,

Whitehall, March 24. C. L. EASTLAKE, Secretary.

THE NEW HOUSES OF PARLIAMENT.

REPORT FROM THE SELECT COMMITTEE.

That the committee have met and considered the subject-matter to them referred, and have examined witnesses, and have come to the following resolution, viz.: That considering the great inconvenience of the present House of Lords, and that such inconvenience will be greatly aggravated by the progress of the new buildings before the commencement of the session of 1844, no delay should take place in the building and preparing the new House of Lords beyond what is absolutely required for the safety of the work; that the architect be directed so to conduct his operations as to secure the occupation of the new House of Lords, with temporary fittings, at the commencement of the session of 1844; that in case the architect in the progress of the work of the new House of Lords shall find that more time will be required in consequence of any apprehension of injurious consequences to the building, he shall report the same to the Commissioners of her Majesty's Woods and Forests, in order that such report may be communicated to this house in due time; that it does not appear to the committee that it is advisable that any alterations in the ventilation of the present House of Lords, which would lead to additional expense, should be adopted; and the committee have directed the minutes of evidence taken before them to be laid before your Lordships.—*March* 13.

A return made to the House of Commons, published 27th ult., states that the total amount already expended for building the new Houses of Parliament is £380,183 10*s.*; the amount voted has been £138,500, and consequently £58,016 10*s.* is in hand unexpended, which will be required for works now in progress of completion. It is estimated that a further sum of £578,424 12*s.* 9*d.* will be required to complete the buildings. The total amount of Mr. Barry's estimate will therefore be £1,016,924 12*s.* 9*d.*, besides what will be required for completing the landing-places, making good the pavings, furniture, and fittings, and for decorations by works of art.

The House of Commons, on the 27th ult., voted an additional grant of £140,000 towards the works.

NEW INVENTIONS AND IMPROVEMENTS.

DREDGE'S SUSPENSION BRIDGE.

The very economical, simple, and powerful principles of the lever in the construction of bridges, may be illustrated thus. A bridge is two arms united at the ends of the chains, the centre, where weight begins and increases from thence progressively, as the chains increase in magnitude and power to the points of suspension. This is effected by an oblique instead of a vertical connection of the platform to the main chains, which fixes all horizontal force in the horizontal line, and gives to the stability of a bridge the most valuable assistance, as is proved by the numerous bridges already erected upon the principle in various parts of Great Britain.

Its truth may also be easily understood by the following experiments. Cut the chains in the middle and the bridge will stand as firm as ever, there being no strain there; then cut the platform in the middle and it will be separated into two independent brackets, each supported by the chains and the strength of the horizontal line against the abutment. The force required to resist this tendency, is a measure of the power conferred upon the bridge, by reason of the oblique connexion of the horizontal line to the chains, independent of the advantage gained by tapering them. On the other hand, cut the chains of a common bridge at the centre, it will destroy the structure; or cut the platform in the middle and leave the chains entire, then it will be seen that there is no tendency of thrust against the abutments, nor any horizontal power in the platform, and that it is the chains only which sustain the structure. In a chain or rope in a pendent curve this cannot be avoided, but in a bridge which consists of curved and horizontal lines, it is clear that the vertical and horizontal forces should be divided, as it is sufficient for the chains in any bridge, in their position of reduced power, to support themselves, the platform and the transit loads; and, independently, it is very clear that the horizontal force should not be in the chains to facilitate their destruction, but in the horizontal line, where it cannot act in the direction of gravity, but where it is as essentially useful towards the maintenance of the structure, as are the chains themselves. It may be remarked that this system facilitates the manufacture of bridges, out of the cheapest and most durable materials—it enables their strength to be computed as easily as the contents of a block of marble is ascertained—requires but one lamina of timber for the roadways, and presents but little surface of resistance, therefore the wind cannot affect it, nor is any longitudinal trussing required, as in other bridges, whose equilibrium is easily affected by the slightest force, because they rest on their centres, similar to the logan stone.

A. Z.

IMPROVEMENTS IN METAL FOR SHIPS, &c.

Mr. William Fairbairn, of Manchester, engineer, has obtained a patent for "*certain improvements in the construction of metal ships, boats, and other vessels; and in the preparation of metal plates to be used therein.*"—They consist in preparing or rolling the iron intended to be used in the construction of ships and vessels, by forming at each edge, and the whole length of the plate, a raised border,—or, in other words, the plate is made at each side or edge, where the rivets pass through, something like double the thickness of any other part of the plate: one side of the plate being plain, which is to be the outside in the construction of a vessel, the other side having two projecting edges, or borders. The rivet-holes on the plain side of each plate are to be countersunk, so that the head of the rivet may be flat or flush with the face of the plate; and in joining two or more plates together, they are not to overlap each other, as hitherto practised, but the plates are placed with their edges together; and behind the two is placed a metal band, bar, or rib, perforated with a double row of holes, to correspond with the holes in the edge of each plate, and the whole are firmly rivetted together so as to form a water-tight joint; and where greater security or strength is required, the metal bands or bars are made in the form of a T, or with a projection on the back side; by this arrangement the resistance of a vessel in the water will not be so great, and the plates at the parts where the rivets pass through will be equal in strength to any other part of the plate; whereas, in those of ordinary construction, the plates are considerably weakened by making the rivet-holes, as such parts have always been found to give way when the plate itself has remained entire.—*Record of Patents.*

IMPROVEMENTS IN CHIMNIES.

M. Eugene de Varroc, of Bryanstone-street, Portman-square, has obtained a patent for "*apparatus to be applied to chimnies to prevent their taking fire, and for rendering sweeping chimnies unnecessary.*"—This invention relates to the application of reticulated metal surfaces, at the commencement, or near the entrance, of the chimney, in order to prevent the passing of the flame, and also to intercept the soot. The apparatus consists of two cylinders of wire-cloth, one within the other, but so constructed that the surfaces of the two cylinders touch, or are in contact with each other. The inventor prefers to make the cylinders of wire-cloth, having sixty-four holes to the square inch, or closely perforated metal plates may be employed, but such will not be found as useful as wire-cloth. The cylinder, which is mounted upon an axis, is fixed in the chimney, as near the fire as convenient, the flue or chimney being so constructed as to prevent any passage for the smoke but through the double-wire cylinder, the wires forming the reticulate, or open work, of one cylinder, being made to cross those of the other cylinder. By this arrangement the flames and soot will be prevented from passing through the cylinder; but there will be sufficient draught through the cylinder for the fire, and the chimney beyond the apparatus will not be coated with soot, the same being deposited on or about the apparatus, which will require to be brushed off every morning, and, if desired, the cylinder can be turned partially round, so as to present another part of its periphery. A modification of this apparatus, composed of a number of perforated plates, and arranged in a rectangular form, is shown, as being applied to the chimney of a steam-engine boiler; in which case there are brushes constructed for clearing the same occasionally from soot.—*Ibid.*

A FIRE ESCAPE.

A correspondent suggests the following simple plan for a fire escape:—

1st. Two ropes of 40 feet in length, each attached to a small chain also 40 feet in length, the end of each chain armed with a spring hook.

2nd. A stout sack of incombustible material (like the fire-proof dresses), open mouthed, with a metallic rim, about four feet deep, and wide enough to hold two persons, with two spring hooks on the opposite sides of the metallic rim, and connected therewith by a small chain of 9 inches long.

These articles should be brought to the spot on the first alarm of fire by a police constable. One rope and chain should be carried into the house next adjoining on the right of the one on fire, and while the rope is held fast, the chain should be dropt from the upper window till it touches the pavement; and the same should be done with the other rope and chain from the house on the left side; the two chains should then be hooked together by the policemen or neighbours. The escape sack should immediately be attached to the centre of the combined chains, and be rapidly drawn up to any window where a person may appear in danger. The moment the individual has got into the sack, one rope must be eased off, so as to allow the other rope to become perpendicular, when the rescued party may be taken in at a lower window of the neighbouring house, or lowered to the pavement; the rescuers giving the rope a half turn round a bed post, so that the lowering may be effected discreetly. It need scarcely be added, that this operation may be repeated several times in a minute, if there should be more individuals to be rescued. The sack, when manufactured, should be steeped in some solution prepared to resist combustion, and care should be taken that the ropes are not unnecessarily exposed to flame.

FLAX MILL AT CASSANO, IN LOMBARDY.

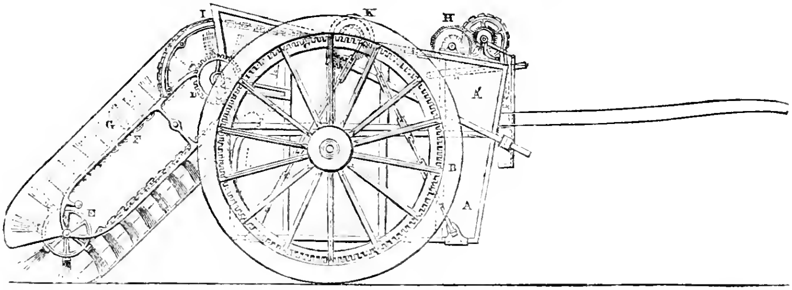
A flax and power loom mill has been established at Cassano, which has excited a good deal of attention in Italy. It belongs to Messrs. Battaglia and Co., and the works were erected by Mr. Albano, C. E., of London. The mill is for flax and hemp, and is divided into three compartments, containing upwards of 8000 spindles, set in motion by a water-wheel worked by the Adda, and 16 ft. in diameter, by 21 ft. or 24 ft. broad. This wheel is of cast iron, except the floats, which are of sheet iron, and the whole weighs 36 tons. To this wheel are attached apparatus for governing the velocity of the machinery, lifting weights to the upper stories, and working fire-engines. In the factory is also included a steam drying apparatus. Altogether the arrangements of the establishment and the adaptation of the machinery are looked upon as conferring great credit on the engineer, and has given great satisfaction to all parties concerned.

THE THAMES TUNNEL.

This important undertaking was opened for foot passengers on the 25th of March last. Thus, after many years of anxiety and difficulties, perhaps without parallel in the history of great Public Works, the practicability of forming a thoroughfare for carriages and foot passengers under a deep navigable river, and without interruption to the navigation, is proved and executed. The obstacles, which have from time to time impeded, and all but stopped the progress of the Tunnel, have been numerous. The work was commenced in 1825, but was stopped in 1828, by an irruption of the Thames. From that time to the spring of 1835 no progress was made. In this year, under the sanction of an Act of Parliament, the Treasury allowed the Exchequer Loan Commissioners to advance, out of the grant voted for Public Works, the money necessary to complete the Tunnel; and it was again commenced and has been continued with few but inevitable interruptions and delays to the present time, when, as the Directors have stated, it is securely completed, and is now thrown open to the Public as a thoroughfare for foot passengers. The two roadways for carriages under the river are also perfectly completed. From its commencement to the present date there have been but 11 years within which the excavation could be carried on. And during this time, for nearly two years or ninety-nine weeks, the works were suspended from circumstances beyond the control of either the Directors or the Engineer. The work has been in fact executed in about 9 years of actual work, at a cost of about £446,000, including property and expenses of every kind, with the particulars of which the Proprietors have been accurately and annually acquainted. The actual Tunnel of 1200 feet was executed in eight years. The Carriage-way descents are now alone wanting to complete the work. They are susceptible of being contracted for in the ordinary way.

The Nelson Monument.—The whole of the leaves, roses, and parts of the Corinthian capital, to be placed on Nelson's monument, Trafalgar-square, have now been cast at the foundry in the Royal Arsenal, Woolwich, with the exception of four volutes. The latter ornaments are most elaborate in their detail, and some idea of the difficulty of making a casting in one piece may be formed, when it is stated that the mould, before it is put together, has to be arranged from about 300 distinct parts, and great doubts are entertained of the artist, Mr. Clark, being able to cast the requisite quantity of metal in the peculiar form of this beautiful and graceful ornament. He is resolved, however, to make the attempt, and confidently anticipates being able to complete the undertaking with from 10 to 13 cwt. of brass. Had the usual mode been adopted the casting could not have been effected with less than about 40 cwt. of metal.

WHITWORTH'S PATENT SWEEPING MACHINE.



This machine, lately brought into operation in the town of Manchester, where it excited a considerable deal of public attention, has lately been introduced into the metropolis, and is now employed in cleaning Regent-street. It is the invention of Mr. Whitworth, of the firm of Messrs. Whitworth and Co., of Manchester, engineers, by whom it has been patented. The principle of the invention consists in employing the rotary motion of locomotive wheels, moved by horse or other power, to raise the loose soil from the surface of the ground and deposit it in a vehicle attached. The apparatus for this purpose is simple in its construction; it consists of a series of brooms (3 ft. wide) suspended from a light frame of wrought iron, hung behind a cart, the body of which is placed near the ground, for greater facility in loading. The draught is easy for two horses, and throughout the process of filling, scarcely a larger amount of force is required than would be necessary to draw the full cart an equal distance.

The following description of the machine by a reference to the accompanying engraving, will explain its action. The cart is constructed with plate iron, and consists of two parts, A. A: the lower part A is suspended to the upper part, and when filled is lowered and replaced with an empty one. To the off-side wheel, B, is attached, on the inside, a cog-wheel, C, which works into a pinion, D, on the end of a shaft the length of the back part of the cart, and fixed thereon are two pullies, 1 ft. diameter and 2 ft. 4 in. apart: two other corresponding pullies, E, are fixed upon a lower shaft, which is suspended to the upper shaft by a wrought iron frame, and over these pulleys pass two endless chains F, to which the brooms G, consisting of 29 rows, each 3 ft. 4 in. long, are attached. It will thus be seen, that when the large wheel of the cart is set in motion, it will, by means of the large spur wheel C, turn the pinion D, and with it the pulleys and the endless chain and brooms that pass over them; and as these brooms come in contact with the road, they sweep the mud up the inclined plane into the bottom part of the cart A. For the purpose of raising the brooms from off the ground there is an apparatus, H, consisting of an endless screw working into a bevel wheel upon a shaft which passes across the top of the cart; upon this shaft are fixed two pulleys, to which are attached two chains, which pass along the top of the cart and over the quadrants I, at the back, and there fixed to the iron frame of the apparatus,—so that when the endless screw is turned the chains are coiled round the pulleys, and raise the apparatus to any height it may be requisite. For the purpose of removing or emptying the lower portion of the cart, it must be raised to a horizontal position; as this apparatus is raised, it throws itself out of gear by means of a lever attached to a clutch fixed on the end of the pinion shaft D. To the apparatus H there is another motion attached for regulating the pressure of the brooms on the ground, according to the state of the weather and the nature of the surface, consisting of a series of weights in the box in front, suspended to two chains, which pass over pulleys on the axle of a wheel that works into another wheel on the same shaft as the first wheel described of the apparatus H.

There is also another apparatus, K, for raising and lowering the lower part of the cart, consisting of an endless screw working into a cog-wheel, the shaft of which passes across the top of the cart, and on each end are pulleys, round which chains are coiled that suspend the cart on each side.

Provision is made for letting off the water collected in the cart, by means of a pipe, having its interior orifice some inches above the level of the mud after settlement: the cart, when full, is drawn to the side of the street, at some distance from a sewer grid, and the pipe plug being withdrawn, the water flows into the channel. A slight modification of the original form of the machine, by bevelling the cogs of the large spur wheel, C, throws the machinery more to the near side, and enables it to sweep close up to the curb-stone of the foot-pavement; and the bands before required to clean out the gutters are now dispensed with. An indicator, attached to the side of the sweeping apparatus, shows the extent of surface swept during the day, and acts as a useful check on the driver. It also affords the opportunity of hiring horses to work the machine over a given quantity of surface, the rate of hire being per 1000 yards actually swept.—This will be found convenient where parties working the machine do not keep their own horses, and will tend to facilitate the introduction of the new system under management of the local authorities.

Where provision cannot be conveniently made in large towns for deposit in yards at proper intervals, the patent machine is constructed of two parts, as above described, viz., an upper, A', carrying the sweeping apparatus, and a lower, A, consisting of a loose box, suspended from the upper, and capable of easy detachment. Each machine having two or more of these boxes, A, may be kept constantly at work, depositing the full box in a suitable place, and taking up an empty box before provided,—a skeleton cart being afterwards employed to convey the loaded boxes to the place of ultimate deposit. No difficulty has been found to arise in the management of the machine by ordinary drivers. It has been worked regularly on every kind of street surface—the round and square set stone,—the Macadamized road,—and the wood pavement; all of which are found in the districts before mentioned. Its peculiar advantage, as applied to wood pavement, in preventing the slippery state of the surface so much complained of, has attracted particular attention, and will, no doubt, tend to facilitate the general introduction of that useful invention. By the use of proper precautions in cleaning and oiling the machine before setting it to work, the friction of the working parts may be materially reduced,—a point of great importance, in reference both to the consumption of horse power and the cost of repairs. The wear of the brooms, which at first was considerable, has been diminished more than one-half, by the action of the regulating weights before mentioned. A product of South America, called by the Portuguese "Piassava," forms an excellent material for the beard of the brooms, having great pliancy and strength combined, and also remarkable degree of durability.

Two machines are advantageously worked together, one a little in advance of the other. Not only is the operation of cleansing a particular street thus effected more rapidly, but the two drivers can occasionally assist each other, and one of them (at higher wages) may exercise a supervision over both machines.

The success of the operation is no less remarkable than its novelty. Proceeding at a moderate speed through the public streets, the cart leaves behind it a well swept tract, which forms a striking contrast with the adjacent ground. Though of the full size of a common cart, it has repeatedly filled itself in the space of six minutes from the principal thoroughfares of Manchester. This fact, while it proves the efficiency of the new apparatus, proves also the necessity of a change in the present system of street cleaning.

Another Great Blast at Dover.—On Wednesday, 1st March, about four o'clock, another great blast took place at the South-eastern Railway works, a little beyond the Rounddown cliff. This blast, as compared with that at the Rounddown (when 18,500 lb. of gunpowder were instantaneously ignited), was comparatively insignificant; but when we mention that 7000 lb. were fired at the present explosion, it will be seen that this insignificance was only comparative. The present operations, like the blast on the 26th January, were conducted by Mr. Cubitt, the engineer-in-chief to the South-eastern Railway, who, with Lieutenant Hutchinson and a number of the directors of the company, were present to-day, witnessing the blast. The effect of this blast has been quite as successful as that which effected the destruction of Rounddown. About 50,000 yards of chalk have been dislodged, ignition being communicated by the voltaic battery. Nine chambers were formed in the cliff, about ninety feet from its top, the object being to blow away the crown of the cliff, to render it safe for the railway carriages to pass on the sea wall under it. Like the explosion on the 26th of January, the present was effected with very little noise and smoke. The instant ignition was communicated the cliffs around trembled, and the immense mass of chalk burst out with a low booming noise, and the ruins were gently, though majestically, thrown down on the beach below; but, instead of, like those of the Rounddown, shoot out into the sea about 1,000 feet, they scarcely, we should say, extended 200 feet in any direction, after reaching the base of the cliff.

STEAM NAVIGATION.

"VIRAGO" STEAM FRIGATE.

The *Virago* is one of the second class frigates belonging to our service. Her dimensions are as follow:—Length between perpendiculars, 180 ft.; keel, 156 ft.; extreme breadth, 36 ft.; breadth for tonnage, 35 ft. 8½ in.; moulded breadth, 35 ft.; depth in hold, 21 ft.; tonnage, 994, M. N. She is fitted with two engines, of the collective power of 300 horses, manufactured by Messrs. Boulton, Watt, and Co., which are eminently novel in their arrangement, occupying less space than any yet employed in her Majesty's navy or otherwise; combining great strength with lightness of construction—facility of access to all the working parts with a ready and simple mode of handling them, being stopped and started with as much ease as if they were intended for river use. Each cylinder is supported upon a foundation plate connected with the condensers, situated in the middle line, forming one casting, and containing the two air pumps, which are worked by an auxillary beam from a crank on the engine shaft; this arrangement having been first adopted by them as far back as June, 1841 (see our *Journal*, Feb. 1842), and which arrangement they have patented with other improvements in the oscillating engine. The steam can be expanded at various parts of the stroke, and the valves for that purpose are simple, and work without the usual noise attending those generally employed. There are four boilers, situated close to each other, but having a clear passage round the sides of 18 inches in width. They have stop-valves to each, so that they may be worked separate or together, as occasion may require. There are 16 fire places, and two firing floors—one forward, towards the engines, the other abaft—to which access is afforded by the above mentioned passage of 18 inches. The chimney is surrounded by a water case, from which the boilers are fed with water at nearly a boiling temperature, by which a saving of fuel is effected, and the risk of fire diminished. This plan was originally adopted by this firm shortly after the destruction of the *Prince Regent* by fire in 1817.

The entire of the boilers and steam-chest is covered with felt, two inches in thickness, sewed on to canvas, protected by inch deal with iron tongues, and finally coated with sheet lead to prevent any leak from the deck saturating either the wood or the felt. On each side of the engine and boilers are ranged the coal boxes, extending from bulkhead to bulkhead, and calculated to hold 23 days' consumption; the machinery is there protected from shot by the thickness of the stratum of coal, while the greater part of the engine is considerably below the load line.

The following are some of the principal dimensions of the engines:—Diameter of cylinders, 64¾ in.; length of stroke, 5 ft.; connecting rod, 8 ft.; diameter of paddle wheel, 25 ft.; boards, 8 ft. long in two widths, each 12 in. The entire weight of these engines, boilers, and coal boxes, are 15 tons under that given to the Admiralty in the tender, being little more than 13½ cwt. per horse.

On the 11th instant an experimental trip, for a short distance down the river, was made in the presence of the government engineers, with which we understand they were perfectly satisfied. They will shortly proceed to Chatham, to be fitted with her rigging, &c., when it is presumed she will be forthwith commissioned.

The "Great Britain."—At a meeting of the Proprietors, held last month, the Directors reported that *The Great Britain* is in a very forward state. The frame and hull are complete. The whole of the upper decks, as well as the decks of the forecastle, forecabins, and aftercabins, are laid and caulked; nearly the whole of the state rooms, and other joiner's work, is finished. The forehold, afterhold, and iron coal decks before the boilers and abaft the engines, are nearly finished. The boilers and funnel are fixed in their places, as are the cylinders, condensers, air-pumps, and other weighty parts of the engines. To add to her strength and diminish the apprehension of fire, the decks and partitions of the body of the ship occupied by the engines, &c., will be fitted up in iron. Nearly all the masts and spars are made, and should nothing unforeseen arise, she may be floated out within three months.—[The Directors take good care that the public shall be kept in ignorance of their proceedings as much as possible; for they will not allow any one to inspect the vessel or their works at Bristol, without an order signed by two Directors, and a contribution of 5*s* towards the sick fund of the workmen. Whoever heard of such a demand? Government allow the public freely to view all the works that are going forward in the public docks, and most of our first engineers will permit any respectable person to visit their works without such an extortionate demand. Lately a professional gentleman applied at the works for admission, and obtained an order from the Managing Director for his admittance, but was told by the porter that he must first pay 5*s*. for his admittance, which he very properly declined to pay, and consequently left in disgust without seeing the vessel.—Editor.]

The "Penelope" Steam Frigate.—This large Man-of-War Frigate, which has been lengthened for the purpose of converting it into a first-class steam frigate, has been towed up the river Thames from Chatham to Messrs. Seaward's Wharf at Limehouse, to receive her engines. The engines are constructed on the Gorgon direct action principle, and occupy, comparatively speaking, a very small space for engines of their magnitude. The cylinders are 92 inches diameter, and 7 feet stroke, at 17 strokes per minute, the collective nominal power of the two engines is 680 horses, but she can be worked up to 750 or 800 H. P. without incurring the slightest risk. She is fitted with Hall's patent condensers, and an ingenious contrivance for altering the throw of the eccentric rod which works the steam valves, by this contrivance the steam can be expanded to any degree, without the aid of an expansion valve; the air-pumps are of solid brass, there is also an ingenious contrivance for disconnecting the paddle-wheel shafts different to any before adopted. There are four boilers, which are tubular and only 9 feet long; the fire-grate is under the boiler; the fire rises from the grate up the back and returns through the tube to the front, it then returns again over the top to the up-take in the centre of the four boilers, which are placed in pairs, back to back. The chimney funnel is made like a telescope, the upper half slides down. When the vessel is completed, we hope that we shall be able to give a more minute description of the several improvements that we have now but slightly alluded to.

The Hindostan Steam-ship.—This steamer, it will be remembered, left Southampton on the 24th September for Calcutta. She arrived at Madras on the 20th of December, having, including delays at the various intermediate ports of call, made the passage in 87 days. The time she was under steam was under 60 days, leaving 27 for stoppages and delays. She averaged 200 miles per day. She had 110 passengers to the Mauritius, and landed 25 at Point de Galla, Ceylon. The *Hindostan* proceeded on to Calcutta, whence she was to sail on the 14th of January for Suez. Captain Moresby, the commander, gives the following account of her performance on the voyage from England to India:—"This vessel is uncommonly easy in a head sea and contrary winds; she then shows off her power and good qualities to advantage; she neither rolls nor pitches much, steers well, and is easily managed in turning; sail when set does not increase her speed much, beyond what full power of steam will give her; it has one advantage—sail when set, the vessel requires less steam, therefore a saving of fuel. With a beam sea she seldom rolls at all; when steaming head to sea and wind, is very dry on deck, and does not take in water forward—instance the voyage from Ascension to the Cape of Good Hope against a strong south-east trade wind, she averaged against wind and current 199 miles per day. The north-east monsoon from Ceylon (Point de Galla) to Madras has been strong with a head sea against her and a current of 22 to 24 miles per day against her yet she has made the distance in three days one hour."

Steam Navigation.—During the last month, a new steam vessel, fitted with a single engine of 30 horse power, has made several trips up and down the river. She has been built for the Watermen's Steam Packet Company by Mr. David Napier, of Millwall, whose two fast boats, the *Eclipse* and the *Isle of Thanet*, excited great attention on the Ramsgate and Margate station last year. The hull of the new vessel is formed of iron, and has a false bottom, which forms a condenser. The steam passes into the condenser, and cold water under and over it. The machinery occupies a very small space, and the consumption of fuel does not exceed a ton and a half per day. With these very small means, Mr. Napier has succeeded in obtaining an extraordinary speed. Her ordinary speed with the tide is stated to be 18 miles an hour; but she is said to have actually proceeded down the river with the ebb tide at the rate of 19 or 20 miles an hour. In one of her recent trips she performed the distance from London Bridge to Greenwich Hospital, exactly 5 miles, in 16 minutes, and on the following afternoon the same distance was effected in one minute less. She is to be called *Waterman, No.* 9, and is intended to ply between the Adelphi pier and Woolwich.

The largest Steam Frigate in the Navy.—The Lords Commissioners of the Admiralty last year approved of a plan submitted by Mr. Oliver Lang, Master-shipwright of the Woolwich Dockyard, of a steam frigate on a far larger scale of dimensions and power than any hitherto constructed, and ordered her to be built at Woolwich, and named the *Terrible*. It is now contemplated that this splendid steam frigate shall be built at Deptford Dockyard on the same slip from which the *Worcester* 50 gun ship will shortly be launched. She is to be of the following dimensions:—

	Feet.	Inches.
Length between perdendiculars	226	0
Keel for tonnage	196	10¼
Breadth extreme	42	0
Depth in hold	27	0
Burden in tons	1847	

She is to be supplied with Maudslay and Field's patent double cylinder marine engines of 800 H. P. The cylinders will be 72 inches in diameter, and the erection of the engines alone has been contracted for at the cost, including the boilers, of the large sum of £40,250. The engine-room will be of the following splendid dimensions:—75 ft. long, 38 ft. broad, and 27 ft. deep; and the weight of the engines and requisite gear connected with them will be upwards of 500 tons. The diameter of the paddle-wheels is to be 34 ft. by 13 ft in breadth. The coal-boxes will contain 800 tons of coals; and altogether this great vessel will far exceed in length and other important points the largest ship-of-the-line ever constructed in this country.—*Times*.

St. Petersburg.—A joint-stock company has been formed for the purpose of establishing a communication by steam boats along the south coast of Lake Ladoga, between Schlusselburg and Sermur, at the mouth of the Swir, and along the coast of Friedland, between Schlusselburg and Sest bol the boat to touch at Kexholm, and the coasts of Lennowets and Walgam. At present 800 vessels from Sermur annually navigate the lake.

Portsmouth Dock-yard.—The Hon. Captain Corry, one of the Lords of the Admiralty, and Captain Brandreth, of the Royal Engineers, the Civil Engineer to the Admiralty, have visited this dock-yard during the last month upon official business. It is understood that one of the objects they had in view was to ascertain the most eligible position at the north part of the yard to make a basin for steam vessels of the largest class, as the Commissioners of the Admiralty have it in contemplation to make this port, as well as Woolwich, a rendezvous for the equipment of steamers. A site has been selected which it is considered will answer the purpose.

MISCELLANEA.

IMPROVEMENTS IN LIVERPOOL. Most of our readers are aware of the contemplated alterations in the vicinity known for many years as the New Haymarket, which, being now numbered amongst the things that were, the surrounding straggling houses, timber-yards, &c. are gradually disappearing and giving place to magnificent edifices, which will impress upon strangers entering the town some idea of its immense wealth, extent, and importance. The façade erected at the terminus of the Liverpool and Manchester and Grand Junction Railways, was the first great step towards forwarding this desideratum. The well known skill of Mr. Elmes, of London, having been called into requisition, (whose designs have met with universal approval) we may with becoming pride and pleasure look forward to the completion of the Assize Courts and St. George's Hall within the time stipulated. From the top of St. John's-lane, extending along the west side of Lime-street to Ranelagh-street, a distance of between four hundred and five hundred yards, the entire range of houses, sheds &c., are to be pulled down, the space widened, and buildings of suitable magnitude erected, which, when accomplished, we may with some degree of pride point to this locality as the centre of attraction in the good old town. Amongst the improvements above alluded to, we have been favoured with an inspection of the plans and elevations for an extensive and first-rate hotel, in the plain Italian style of architecture, which will be situated at the corner of St. John's-lane and Roe-street, the entrance facing the colonnade of the Assize Courts; and certainly a more desirable situation could not have been selected. The arrangements are to be on the most approved modern scale, and a handsome structure, we have no doubt, will be erected.—*Liverpool Mail.*

LIVERPOOL.—The works at the intended Albert Dock and warehouse, on the west side of the Salthouse Dock, are rapidly advancing. The operation of piling is at present the principal occupation, and for this purpose several steam-engines have been erected on the ground. Excavation is also going on in the centre of the ground, and building in other parts. The entrance into the Salthouse Dock is already formed, and the piling for the sea-wall is advancing. Several hundreds of men are employed on the works, and all seems to go on with great order, expedition, and precision.

THE ROYAL EXCHANGE.—Great progress is now making in placing the sculptured coping above the columns, as well as over the other parts of the building. The transition is more striking on account of the elaborate workmanship being all performed ere the stone is raised, and but a short time is now required with the improved machinery at command to fix it at once in its position.

THE ALPS.—A canal is in the course of formation for the purpose of irrigating the plains of Provence, in the summer months, with the waters which pour down from the Alps. Eight hundred labourers are at work on the canal, on which 1,200,000 francs have already been expended.

CLAUGHTON AND BIRKENHEAD WATERWORKS.—The spirited company connected with this enterprise, which will confer the most invaluable boon on the inhabitants of Birkenhead, having, after immense labour, found abundance of water, the first stone of the works about to be erected was laid by John Jackson, Esq., on Tuesday, 14th March. The engine, which is thirty-horse power, is now in course of completion by Messrs Jones and Potts, of Neston. The buildings are to be erected by Messrs. Walker and Craven.

GRAND RAILWAY JUNCTION.—A contract for forming the junction between the Manchester and Liverpool and the Manchester and Leeds Railways, at Hunt's Bank, has just been made between Mr. Pauling, of Manchester, and the former body. It will be carried on arches some 18 or 20 feet above the level of the streets; its route will be through Salford. Report states that the contract is for something near £70,000, and that the work is to be completed in all in September next. This will unite the towns of Hull and Liverpool by one continuous railway, and prove the means of saving at least ten days in the transit of goods, when contrasted with the canal conveyance.—*Liverpool Mail.*

MACHINERY FOR EXPORTATION.—We understand the machine-makers of Lancashire and Yorkshire are busier than they have been for some years, their orders being principally for the continental market; indeed, ever since the order in council was issued permitting the free exportation of cotton machinery, the trade of machine-making for the use of our foreign rival manufacturers has been more extensive than ever.

MECHANICAL IMPROVEMENTS.—An ingenious application of the common reading-desk to the purposes of newspaper reading has been recently contrived by a Mr. Joseph Schlesinger, an engineer, at Birmingham. It consists of a sliding stand, which supports a light frame fixed at a convenient angle, and capable of holding one or several newspapers by means of an iron cramp, which is opened by a lever. This apparatus will be a perfect luxury for clubs and offices.

LIST OF NEW PATENTS.

(From Messrs. Robertson's List.)

GRANTED IN ENGLAND FROM FEBRUARY 28, TO MARCH 24, 1843.

Six Months allowed for Enrolment, unless otherwise expressed.

John Heathcoat, and Ambrose Brewin, of Tiverton, lace manufacturers for "*improvements in the manufacture of ornamented net or lace.*"—Sealed Feb. 28.

Gottlieb Boccius, of New-road, Shepherd's Bush, for "*improved arrangements and apparatus for the production and distribution of light.*"—Feb. 28.

George Bell, of Dublin, merchant, for "*improvements in machines for drying wheat, malt, corn, and seeds, and for bolting, dressing, and separating flour, meal, and other like substances.*"—March 1.

John Frearson, of Birmingham, machinist, for "*improvements in fastenings for wearing apparel.*"—March 2.

Thomas Simpson, of Birmingham, manufacturer, for "*an improvement in buckles.*"—March 2.

Masta Joscelin Cooke, of Gray's-inn-square, solicitor, for "*improvements in the manufacture of artificial fuel.*"—March 2.

John Keely, the younger, of Nottingham, dyer, and Alexander Alliott, of Lenton, bleacher, for "*improvements in machinery or apparatus for drying or freeing from liquid or moisture, woollen, cotton, silk, and different fibrous materials, and other substances, and also for stretching certain fibrous materials.*" (A communication.)—March 2.

William Walker, of George-yard, Crown-street, Soho, coach-smith, for "*improvements in the manufacture of springs and axles for carriages.*"—March 2.

Charles White, of Noel-street, Islington, engineer, for "*improvements in machinery for raising and forcing fluids.*"—March 2.

Robert Stirling Newall, of Gateshead, Durham, wire-rope manufacturer, for "*improvements in the manufacture of wire-ropes, and in the apparatus and arrangements for the manufacture of the same.*"—March 7.

William Newton, of Chancery-lane, civil engineer, for "*improvements in machinery or apparatus for making pins.*" (A communication.)—March 6.

James Pilbrow, of Tottenham, engineer, for "*improvements in the application of steam, air, and other vapours and gaseous agents to the production of motive power, and in the machinery and apparatus by which the same are effected.*"—March 7.

William Betts, of Ashford, Kent, railway contractor, and William Taylor, of the same place, plumber, for "*improvements in the manufacture of bricks and tiles.*"—March 8.

William Kenworthy, of Blackburn, Lancaster, cotton spinner, for "*improvements in machinery or apparatus called 'beaming or warping machines.'*" March 11.

Charles Chilton, of Gloucester-street, Curtain-road, and Frederick Braithwaite, of the New-road, engineer, for "*improvements in machinery for cutting or splitting wood for fuel and other purposes.*"—March 16.

Arthur Chilver Tupper, of New Burlington-street, Middlesex, gentleman, for "*improvements in the means of applying carpets and other covering to stairs and steps, and in the construction of stairs and steps.*"—March 16.

Alexander Angus Croll, superintendent of the gas-works, Brick-lane, Middlesex, and William Richards, of the same works, mechanical inspector, for "*improvements in the manufacture of gas for the purposes of illumination, and in apparatus used when transmitting and measuring gas or other fluids.*" March 16.

Angier March Perkins, of Great Coram-street, engineer, for "*improvements in the manufacture and melting of iron, which improvements are applicable for evaporating fluids, and disinfecting oils.*"—March 16.

John Thomas Betts, of Smithfield Bars, gentleman, for "*improvements in the manufacture of metal covers for bottles and certain other vessels, and in the manufacture of sheet metal for such purposes.*" (A communication.—March 16.

Frederick Cook Matchett, of Birmingham, manufacturer, for "*improvements in the manufacture of hinges.*"—March 16.

Martyn John Roberts, of Brynycaran, Carmarthen, gentleman, for "*improvements in the composition of ink, blacking, and black paint.*"—March 16.

James Malam, of Huntingdon, gas engineer, for "*improvements in the manufacture of gas retorts, and in the modes of setting gas retorts.*"—March 16.

William Laycock, of Liverpool, merchant, for "*improvements in constructing houses and such like buildings.*"—March 16.

Wakefield Pim, of the Borough of Kingston-upon-Hull, engineer, for "*certain improvements in the construction or formation of buoys or other water marks.*"—March 18.

Alexander Simon Wolcott, of City-terrace, City-road, machinist, and John Johnson, of Manchester, in the county of Lancaster, machinist, for "*improvements in photography, and in the application of the same to the arts*"—March 18.

William Barker, of Manchester, millwright, for "*improvements in the construction of metallic pistons.*"—March 20.

Solomon Rolinson, of Dudley, Worcester, roll-turner, for "*improvements in the manufacture of shot.*"—March 20.

Joseph Needham Taylor, of Chelsea, captain in Her Majesty's navy, and William Henry Smith, of 33, Fitzroy-square, civil engineer, for "*improvements in breakwaters, beacons, and sound-alarms; also in landing or transmitting persons and goods over or through strata or obstructions of any nature, all of which may be used either separately or in combination.*"—March 21.

Andrew Barclay, engineer and brass founder, Kilmarnock, Scotland, for "*improvements in lustres, chandeliers, pendants, and apparatus connected therewith, to be used with gas, oil, and other substances, which invention is also applicable to other purposes.*"—March 24.

Gregory Seale Walters, of Coleman-street, merchant, for "*improvements in the manufacture of chlorine and chlorides, and in obtaining the oxides and peroxides of manganese in the residuary liquids of such manufacture.*" (A communication.)—March 24.

Alfred Hooper Nevill, of Chicester-place, Grays-inn-road, corn dealer, for "*improvements in preparing lentils and other matters for food.*"—March 24.

EMIGRATION.—LAND SURVEYING IN THE COLONIES.

MR. HENRY CASTLE, Lecturer on Land Surveying and Levelling, at King's College, London, Author of a Treatise on the same subjects, and formerly Boundary Commissioner to the Home District, Upper Canada, is forming a FIELD CLASS on the Circumferentor and the method of Surveying peculiar to new Countries.

Fee for the Course, to commence the 26th April, Five Guineas. Apply at 30, Queen-square, Bloomsbury.

P.S. The College Classes will be resumed at the same time.

LAWRENCE & CO., 55, PARLIAMENT STREET, WESTMINSTER, and 10, YORK PLACE, LAMBETH, Successors to the Patentees and Manufacturers in Zinc to her MAJESTY THE QUEEN DOWAGER. Original makers of Malleable Sheet Zinc, Bars, and Wire. Drawers of Tubes, and Sash-bars. Perforated Zinc, for Larders, Safes, and Blinds. Roofs and Verandas covered with Zinc. Rain Pipes, Chimney Pipes, Cowls, &c. Gutters, Ridges, and Sky Lights. Baths and Zinc Door Plates.

Garden Lights, Wardian Cases, and Conservatories.

N.B. The Trade supplied. Patent Smoke-curers, and Chimney-shafts. Fine Sweedish Steel, wholesale, retail, and for export.

TO BUYERS OF IRON CASTINGS.

UNDERGROUND PIPES, for Gas or Water, Railway Chairs, Wheels and Columns, Beams or Girders for Buildings, Palisading and Coping, Sash Weights, Furnace Bars, Hot Water Pipes, Large Doors, Piles, Posts, and all sorts of heavy castings made very expeditiously to order or pattern.—Apply to James Robertson and Co., Jamaica-street, Glasgow, or G. O. Robertson, Esq., 6, Crescent, Minories, London.

This day, in 8vo., 14s., cloth, lettered. Simpkin and Marshall, London.

A TREATISE ON LAND-SURVEYING AND LEVELLING, with copious Field Notes, Plans, &c., Logarithms and Traverse. By HENRY JOHN CASTLE, late Boundary Commissioner to the Home District, Upper Canada, and Lecturer on Practical Surveying at King's College, London.

"Justifies the promises of the preface—a complete *vade mecum*."—*Atlas*.

"A very useful book—no pains spared to make it so."—*Railway Mag.*

"Invaluable to the young surveyor in our Colonies."—*Shrewsbury News*.

"A useful book on the general subject—a *vade mecum*."—*Surveyor and Engineer*.

"Treated clearly—bids fair to be useful to the student."—*Athenæum*.

THE ARTIZAN.

A Monthly Journal of the Operative Arts. Price 1s.

No. 3, just published, contains the following: 1. The Association of the Proprietors of Steam Shipping. 2. Sanitary arrangements in large towns. 3. Table of the dimensions and cost of Railway Bridges. 4. Expansion of Steam in Locomotives. 5. Carpenter's Mechanical Philosophy. 6. Our Club, No. 3. 7. Transactions of the Institution of Civil Engineers. 8. The London Breweries. 9. Table of Railway Gradients, &c. 10. The Building Arts. 11. Metropolitan Improvements. 12. Report of the Railway Department of the Board of Trade. 13. Anatomy of the Steam Engine, No. 3. 14. Physiology of the Steam Engine, No. 3. 15. Analysis of Books. 16. Marvels of the Day.

The two last heads are intended to contain all that is new in the literature of the arts, and an account of all new discoveries, inventions, and constructions. All the articles are original, and no letters are admitted.

OPINIONS OF THE PRESS.

"Displays technical knowledge, literary ability, and searching investigation."—*Spectator*.

"We are indebted for this searching inquiry to a new scientific periodical of great promise, entitled *The Artizan*."—*Polytechnic Journal*.

"*The Artizan*, a new Journal of good promise, devoted to the same subjects as our own."—*Mechanics' Mag.*

"No. 2 improves upon its predecessor; and the work does much credit to all engaged upon it."—*Monthly Times*.

"We have been presented with the first Number of a London Periodical, called *The Artizan, a Monthly Journal of the Operative Arts*, which we have much pleasure in recommending to those of our readers who are engaged in Engineering and Ship-building, or who take an interest in scientific matters."

"A periodical that would give a decided and unbiassed opinion on those subjects has been much wanted, as most of the scientific journals of the day are too apt to state opinions favourable to the inventor or executor of a work of art, without considering that in so doing they are deceiving the public."—*Greenock Advertiser*.

Simpkin, Marshall, & Co., and all Booksellers.

TRANSPARENT DRAWING AND TRACING PAPER.

REDUCED IN PRICE.—TO CIVIL ENGINEERS, ARCHITECTS, & SURVEYORS.—H. DIXON, after a number of years' study, has made perfect a most beautiful (Crystographic) TRACING PAPER, very transparent, which will take ink, oil, and water colours, without running. The price is very low, and the following are the sizes:—

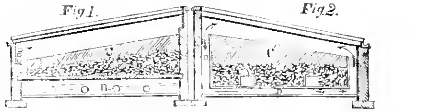
30 by 20	Double Crown	4s.	per quire of 24 sheets.
40 by 30	Double Double Crown .	7s. 6d.	" "
	Yellow Imitation of French 12s.		" "

Also, DRAWING PAPER MADE TRANSPARENT, for Tracing on, all the different sizes from 20 by 15 to 66 by 47 in. Which can be sent to any part of the three Kingdoms, by a remittance of Cash, or a Post Office Order. Address to the MANUFACTURER, H. DIXON, No. 194, Strand, near Temple Bar, London.

THOMSON'S IMPROVEMENTS IN HORTICULTURAL HEATING, &c.

J. THOMSON, late Head Gardener to His Grace the Duke of Northumberland, at Syon House, and for many years in the Garden Establishment of Her Majesty, has introduced an improved mode of applying the Pipe Tank and Trough System, for bottom and top heat to hot houses and other horticultural erections, by which the perpetual nuisance and labour attending the continual renewing of tan, dung, and other fermenting materials, commonly used to produce bottom heat, are obviated. The apparatus can be fixed so as to produce a humid or dry atmosphere at will; and the expence does not exceed half that of any other plan of hot water.

Fig 1. Fig 2.



Pipes for Bottom & Top Heat. Troughs for ditto.

The above plan of applying the Pipe Tank and Trough System of Heating, combined with his newly invented and economical boiler, has been adopted by, and may be seen at, the two largest Horticultural Establishments in Great Britain, viz., Messrs. Lees' Nursery, Hammersmith, and Mr. Wilmot's, Brentford or Isleworth.—Designs and Estimates for warming horticultural erections, public or private buildings, &c., may be obtained on application to J. Thomson, Landscape Gardener, 1, Chapel Place, Hammersmith.

J. T. has applied the above system for bottom heat to pines and for other purposes at Lord Prudhoe's, and several other places in England, with great success, within the last six years.

TO ARCHITECTS, ENGINEERS, SURVEYORS, AND OTHERS.

W. HOBCRAFT respectfully calls the attention of the above, and all persons requiring accurate Rules, Scales, and Mathematical Instruments, that from the advantages he possesses, being a Manufacturer, he is enabled to supply them with goods of a superior quality, at prices reduced considerably below those usually charged, by which from 15 to 25 per cent may be saved. Rules and Scales of every description for Mechanical and Scientific purposes made to order on the shortest notice. Levelling Staves, Optical and Philosophical Instruments, equally reasonable. Merchants, Captains, and the Trade supplied on advantageous terms. Country orders, containing a remittance or an order for payment in London, promptly attended to.

W. Hobcraft, 38, Princes-street, Leicester-square, London.

Books of Instructions, gratis, with Slide Rules.

AMERICAN STEAM EXCAVATING (OTIS', NEW YORK) AND PILE DRIVING MACHINERY.

COMPLETE DRAWINGS to a large scale, together with every detail of these machines, may be had of

GEORGE SPENCER,

26th March, 1842. Draftsman for Machinery and Patents.

G. S. respectfully offers his services to the profession and to patentees in preparing working or finished drawings of every description of machinery.

SEYSSEL ASPHALTE COMPANY, "Claridge's Patent." Established March, 1838.—The extensive patronage which this valuable MINERAL production continues to receive from the most eminent ARCHITECTS and ENGINEERS in this country and abroad, distinguishes it from the numerous fictitious compositions which its reputation gave rise to, but which having been found very inferior to the original material, most of them have ceased to be used. Its merits being well known, it is only necessary to refer to a few of the public works already executed and now in progress.—On the London and Greenwich Railway, and Joint Station, London Bridge, 130,000 superficial feet; several thousand feet at the Great Western, Birmingham, Midland Counties, South-western, Brighton, Blackwall, and other Railways; covering of Arches at the South Metropolitan, Highgate, and Nunhead Cemeteries; the covering of the Casemates at the Perch Rock Battery, Liverpool; the Pavement in Whitehall; the Carriage-drives at the Horse Guards, and at the entrances to the Park by Apsley House; the Cells and other apartments of the new Prison at Hereford; several works at the Stations on the Dublin and Kingstown Railway; and many other public and private works in different parts of England, Ireland, and Scotland.

A Scale of Prices, with Books of Testimonials, can at all times be had at the Company's Depôt, where specimens of its various applications may be seen. J. FARRELL, Secretary.

Seyssel Asphalte Depôt, Stangate, near Westminster Bridge.

March, 1843.

FROM "THE TIMES."

December 5, 1842.

"Many of our readers may, perhaps, remember that some years ago, and previously to the introduction of Asphalte into this country, we expressed our admiration of the pavement, composed of that substance, in Paris, and especially of that in the Place de la Concorde, the whole of which has been long since paved with Asphalte. It now behoves us to point out the piece of Seyssel Asphalte laid down in April, 1838, in Whitehall, opposite the Horse Guards, as equal to the pavement in the Place de la Concorde, or in any part of Paris, and considering that its thickness is only half an inch, its having so long stood the traffic of so great a thoroughfare, without any apparent change, except a greater smoothness of surface, is very remarkable."

PRINCE'S PARK.

TO ARCHITECTS.

ONE HUNDRED GUINEAS will be paid in premiums for the best designs for four Terraces to be erected in the Prince's Park, now in progress near Liverpool.—Plans of the ground and full instructions may be obtained by applying to

Messrs. FOSTER and STEWART, or } Architects, Liverpool.
Messrs. A. and G. WILLIAMS, }

SMOKE NUISANCE.

THE METROPOLITAN IMPROVEMENT SOCIETY having, on the part of the public, determined to get abated the long-existing nuisances arising from furnaces used in the working of steam-engines within the metropolis, are desirous of receiving INFORMATION from public bodies, and also private individuals, who are suffering injury from such NUISANCES, in order that indictments may be preferred against the offenders; the same to be forwarded to James Anderton, Esq., the Honorary Solicitor of the Society, 20, New Bridge Street, Blackfriars, or to the Committee, at the Society's Office, 20, Bedford Street, Strand.

HENRY AUSTIN, Hon. Sec.

THE THAMES TUNNEL IS NOW AT ALL TIMES OPEN TO THE PUBLIC as a Thoroughfare for Foot Passengers, at a Toll of One Penny each.

By order of the Board of Directors,
J. CHARLIER, Clerk of the Company.

Company's Office, 2, Walbrook Buildings, City, 25th March, 1843.

N.B.—Steam Boats to Wapping, from Hungerford, Adelphi, Temple Bar, Blackfriars Bridge, Old Shades, Old Swan, and Adelaide Piers, London Bridge; and by Omnibusses to Rotherhithe from the West-end, and from Gracechurch-street, at every half hour.

ANTI-DRY ROT COMPANY—KYAN'S PATENT.

THE DIRECTORS of this Company having removed one of their 60-ft. hydraulic presses to their Station, City Basin, City Road, desire to draw the attention of the public to the great facilities they now offer for preparing timber of large calibre in a few hours. When the quantity exceeds 100 loads the Directors allow a considerable reduction in price.

GILLOTT'S PATENT FAN STOVE, for Heating and Ventilating Churches, Courts of Law, Hospitals, and all large public Buildings.—It is particularly adapted for drying the walls of newly-built houses, for various manufactures where heat is required, without the possibility of accident by fire, as the apparatus is not required to be on the premises, but the hot air may be conveyed into the manufactory by a pipe, or pipes, and it would not ignite gunpowder. It is invaluable also for ships, as warm or cold air may be propelled into every part of them, either for warmth or ventilation. May be seen in use at J. L. Benham's, 19, Wigmore Street, Cavendish Square, and at 80 Great Queen Street, Lincoln's Inn Fields.

TO AMATEUR TURNERS, CONNOISSEURS, AND OTHERS.
HARD WOODS.

R. HENESEY, of 189, High Holborn, begs to announce that he has on hand a small STOCK of the choicest AFRICAN BLACK WOOD, the only importation for 30 years. This beautiful wood contains no acid, has a remarkably fine grain, is not liable to rust steel, and on this account is particularly recommended to the notice of surgical instrument makers: for eccentric turning its properties are invaluable. R. H. has always on hand at his warehouses Brazilian and French tulip, sandal, and violet woods; also the root of the olive tree, kaibooka, and a greater variety of curious foreign hard woods than can be found in any other establishment in the kingdom.

N.B. An immense assortment of veneers.

TO CARPENTERS AND BUILDERS.

Baltic and American Timber.
Yellow and White Deals, Planks, and Battens.
Yellow and Red Pine ditto.
Spruce ditto, ditto.
Yellow and White Dry Prepared Floor Boards.
Yellow and White Dry Prepared Battens, from ½-in. to 1¼-in. thick.
New Fir Scantling, all sizes.
New Oak ditto.
New and Old Oak Ground Joists and Sleepers.
New Oak Sash Sills.
New Oak Boards and Planks.
New Wide Oak Planks for Coffin Makers.
Fir Slating Laths.
Fir Pantile Laths.
Single and Double Fir Laths.
Double Fir and Oak Sawn Laths for packing Wine.

Mahogany, &c. Reduced Prices.

Apply at WILLIAM CLEAVE'S TIMBER-YARD, 9, Smith-street, Westminster.

WANTED, A PARTNER, in an extensive and well established IRONFOUNDRY and ENGINEERING CONCERN, in full work, in a populous manufacturing district in one of the Midland Counties. To a practical man, with a capital of from £1000 to £2000, the above presents such an opening as is seldom to be met with.—Apply to C. Y., at Messrs. T. Barber and Co.'s, Newhall Street, Birmingham.

TO ARCHITECTS.

A YOUNG MAN wishes to meet with an engagement in an ARCHITECT'S OFFICE, or to superintend the erection of works. Highly respectable references can be given.—Address, prepaid, to A. Z., Mr. Elliott's, 268, High Holborn, London.

SMOKE.—The following remarks on RODDA'S PLAN were made at the meeting of the Leeds Smoke Committee, held Jan. 26, 1843:—

The Rev. J. A. RHODES said, that, if the meeting would permit him, he would mention what plans he knew to be very effectual. He had been for years annoyed at his residence at Mytholm by the smoke arising from the mill of Messrs Robinson and Co., at that place. He had remonstrated with them on the subject, but, being the owner of a mill himself, he thought it best to try to prevent smoke at his own mill, in order that, if he succeeded, he might have good grounds for his remonstrances with Messrs. Robinson and Co. The mill of which he was the owner was that of Messrs. Walker, at Milshay; and at it Mr. Rodda was employed, and he had since seen that gentleman's plan in full operation there, and had examined it closely, and certainly the apparatus had been put up to his (Mr. Rhodes's) entire satisfaction, and was quite effective in preventing smoke.—Mr. MACLEA had had Rodda's plan in use for six months, and he could testify to its good effects.

Mr. HOLDFORTH said that he had found Rodda's plan better than five or six other plans that he had tried. He had persevered in the use of Rodda's apparatus, which prevented smoke, effected a saving in the fuel, and had other advantages—such as raising the steam quickly, and keeping it up a regular height with very little attention on the part of the fireman. As soon as ever smoke was generated, the apparatus possessed means of destroying it; and the only time when there was smoke was when fresh coals were thrown on the fire, and then there was not much smoke, and that was not visible more than half a minute. The coals he was using were unriddled slack, which he found to answer very well, and his mill was quite free from smoke. He believed that Mr. Rodda's plan was applicable to dye-house pans and to all sorts of furnaces except to the rotatory (Brunton's) grates.

Mr. ATKINSON inquired if any plan that was known could prevent a large quantity of smoke being emitted when a fire was first lighted?—Mr. HOLDFORTH replied that Mr. Rodda's did to a great extent.

Mr. LUCCOCK said that Messrs. Pease and Heaton, and also Mr. George, had applied Rodda's plan to their dye-pans, and found it to answer exceedingly well.—Mr HOLDFORTH had seen the plan in operation at Messrs. Pease and Heaton's, and he could testify that it was quite effective. It was only when Mr. Rodda's instructions were not obeyed that smoke was generated. With regard to the best means of ensuring attention on the part of firemen, Mr Holdforth stated how he did with his men. He went to the fireman and said, when the plan was in effective operation, "Now, you see there is no smoke, and you see, if the apparatus is properly attended to, there will be no smoke." "Yes," said the man. "Well, then," replied Mr. Holdforth, "take notice and remember, that if I see any smoke coming out of the top of the chimney, you must take that as a month's notice to quit." This he found had the effect of making the man attentive to his duties; and if he managed well, and to his (Mr. Holdforth's) satisfaction, he occasionally gave him a little reward.

R. RODDA is now in LEEDS, and begs to inform the PROPRIETORS of STEAM ENGINES, &c., in Yorkshire, Lancashire, and elsewhere, that he has REDUCED HIS PRICES, and is also furnished with numerous testimonials as to the perfect success of his plan for CONSUMING SMOKE and SAVING FUEL.—Communications, addressed to 11, Briggate, Leeds, attended to immediately.

DREDGE'S PATENT IRON BRIDGES.

THIS economical and powerful system of construction is founded upon the principles of the lever—therefore, it is adapted for the heaviest traffic on rail and other roads, and for the largest or smallest spans in all situations. It is not half so expensive as timber bridges; and, taking an average of large and small spans on the old principles of suspension, this system admits of the erection of 10 powerful bridges for one, there being so much less material and labour in their construction. The Clifton-bridge, upon this principle, could be erected for £10,000, in six months. The principle was first used by the Victoria Bridge Company, over the Avon at Bath, in 1836, in a bridge 150 feet long, and 19 wide. Afterwards, the government adopted it in five bridges in the Regent's Park; and Sir James Colquhoun, Bart., used it over the Leven, in Scotland; this bridge is 292 feet long and 20 feet wide. Another is erected at Wraysbury, near Windsor, for G. S. Harcourt, Esq., and one across the river Frome, for H. Miller, Esq. The elevation, plan, sections, and description of Mr. Harcourt's bridge is published in the "Architect, Engineer, and Surveyor," No 36. It is 100 feet long and 17 broad, and its cost was less than the centering for a stone bridge of the same magnitude.

*** J. DREDGE will undertake the construction of bridges, and guarantee their stability; and he will take shares in any toll bridges he may erect.

Bath, March 1.

BY HER MAJESTY'S ROYAL LETTERS PATENT.

GERISH'S PATENT DOOR-SPRINGS, FOR CLOSING EVERY DESCRIPTION OF DOOR.—Manufactory, 16, East Road, Hoxton New Town.

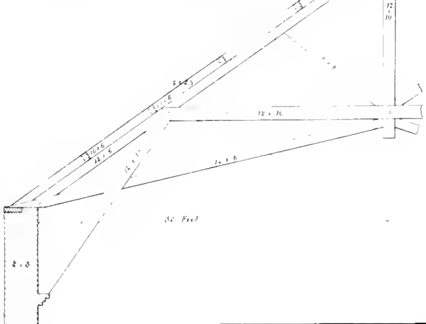
These springs consist of parallel and rising hinges in Brass or Iron, and swing centres for doors opening both ways.

These improved spring-hinges or door-springs merit general attention, as they can be applied to any door, in every situation, without defacing the wood-work; their action is easy and noiseless, neat and not visible when the door is shut, and are made to surpass the best now in use for nearly one half the price; they allow the door to go quite back, and are not likely to get out of repair.

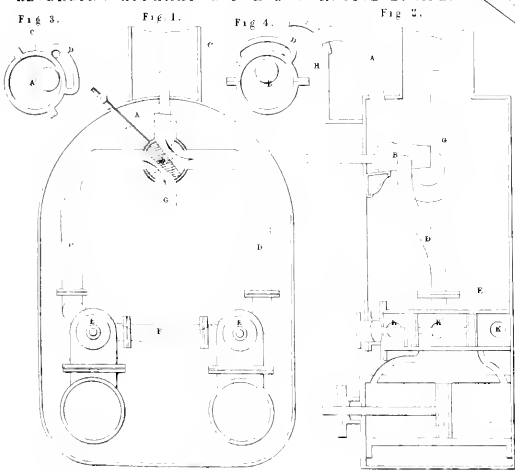
The Swing Centre possesses in a simple combination of power double the strength of any hitherto invented in a much smaller size, and at little more than half the expense.

LITHIC ANTI-CORROSION PAINT, long known for its durable qualities in all climates as a cheap out-door paint for covering Brick Wood, or Iron. Manufactured in Stone or Slate Colours by J. B. WHITE and SONS, Millbank Street, Westminster, Roman Cement Manufacturers.

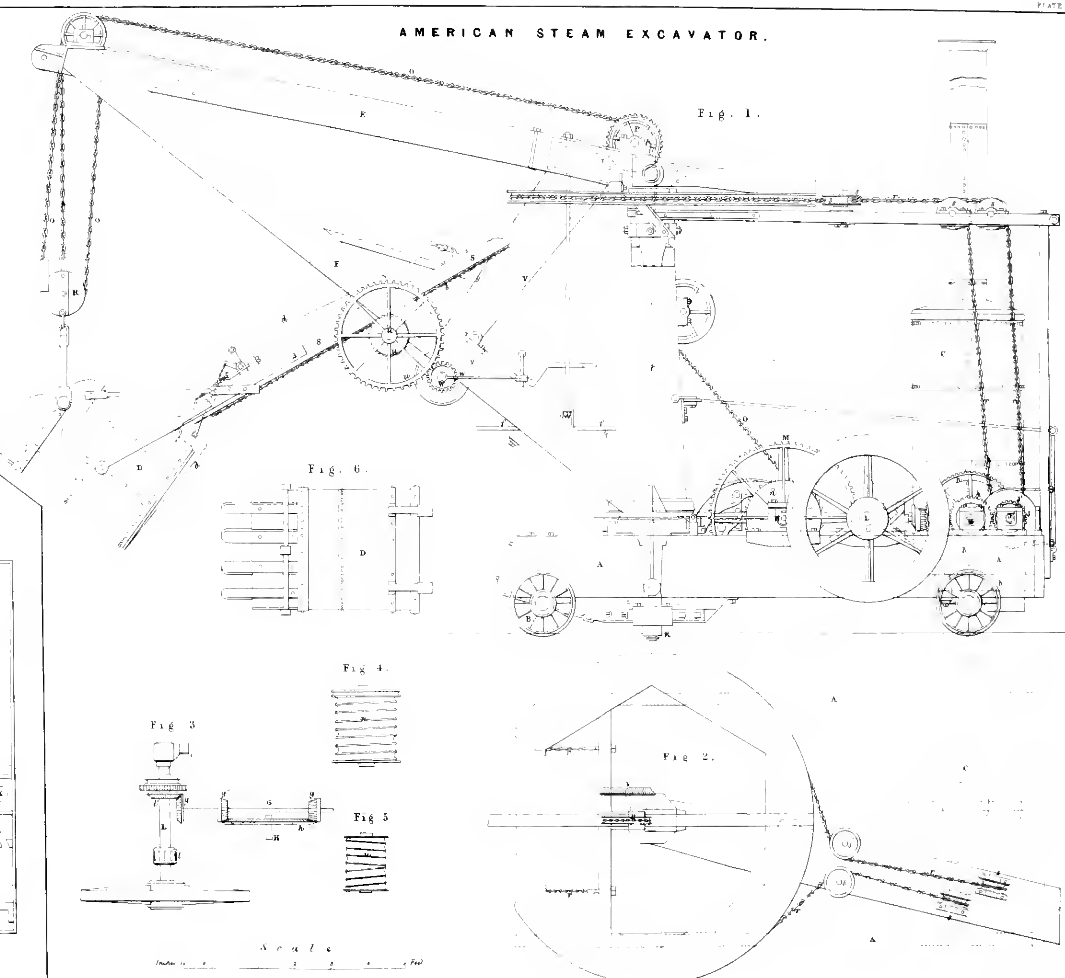
ROOF OVER THE RIDING SCHOOL, NEWCASTLE ON TYNE

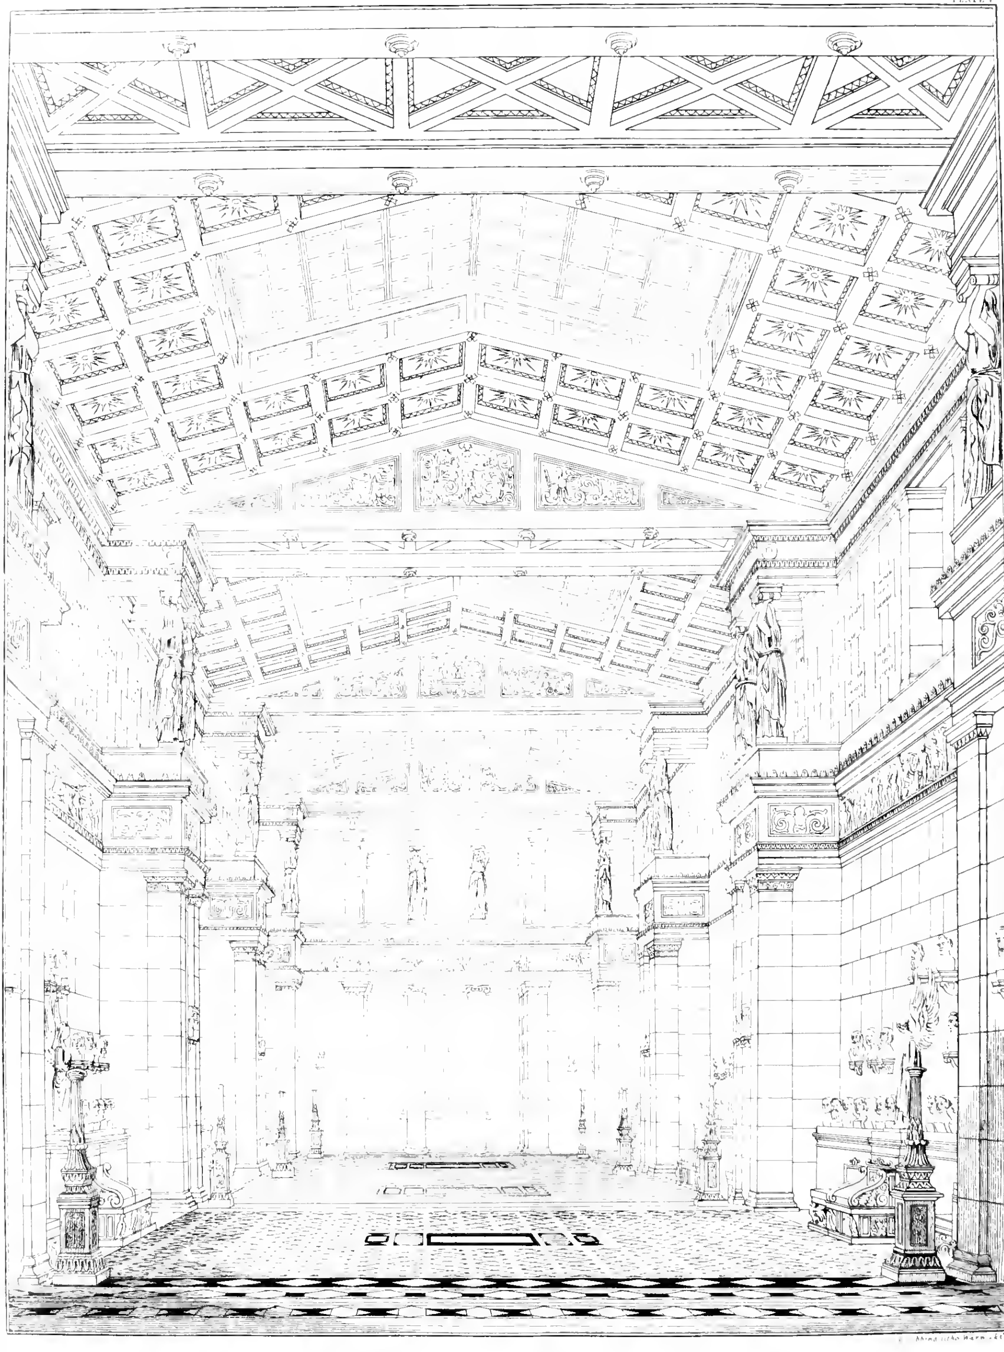


REVERSING APPARATUS FOR LOCOMOTIVE ENGINES



AMERICAN STEAM EXCAVATOR.





INTERIOR of the WALHALLA.

THE AMERICAN STEAM EXCAVATING MACHINE. ("YANKEE GEOLOGIST.")

(With an Engraving, Plate VI.)

This machine, which is the invention of the late Mr. Ottis, of New York, is an application of steam power to the purposes of excavation and dredging; and for the former purpose, appears greatly superior to any thing which has hitherto been achieved in excavating machinery. The accompanying engraving, which has been made expressly for our *Journal*, by Mr. George Spencer, Mechanical Draughtsman, from the original working drawings in his possession, presents the principal side elevation (Fig. 1) of the machine, which brings all the working parts sufficiently into view; Fig. 2, a plan of the horse-shoe pulley and crane top; the dotted lines show the position of the lower framing or stage and boiler; Fig. 3, shows the crank shaft and gearing; Fig. 4, the main drum; Fig. 5, the main drum for working the excavator; and Fig. 6, a plan of the excavator.

The whole of the details of this machine, which are very elaborate and complete, of course cannot be attempted in an article of this nature: we will, however, describe as much of the details and its principal feature as are necessary to a proper understanding of the several movements of the machine, and then describe each of those movements separately. The machine consists of a strong horizontal wooden framing or stage A, mounted upon two pairs of railway wheels B, for locomotion, which run on temporary rails, laid down as may be required; on the one end of the stage is fixed a cylindrical boiler C, and the gearing for turning the crane round. In the middle is placed the gearing for working one of the motions of the excavator D; and, at the other end is placed the wooden crane E, in form similar to an ordinary timber crane, on the diagonal brace of which is placed a platform *f*, on which an assistant stands; and gearing U, for working another motion of the excavator D. To support the machine laterally, strong brackets or arms project on either side, the ends of which are furnished with screws to adjust the machine to the inequalities of the surface of the ground.

The excavator or shovel D, (Figs. 1 and 6,) is formed of stout boiler plate, and is firmly rivetted together; it is of a box shape, having one end open; on the lower edge are four tangs or points, which serve to penetrate and loosen the soil; the other end is hung on swivel hinges, and fastened by a spring *d*, which may be set at liberty by means of the lever and rods *a*, Fig. 1.

The machine is made to perform three distinct movements; 1st, the digging movement; 2nd, the turning movement, and 3rd, the locomotive movvement.

The Digging Movement consists of two motions, one for drawing the excavator forward, and the other for driving it into the ground, both of which is done simultaneously; the first motion is performed in the following manner. On the horizontal stage A, and in front of the boiler C, is placed a small high-pressure engine, (not shown in the engraving,) the connecting rod of which acts upon the crank *c*, and gives a rotary motion to the shaft L, and with it the pinion *l*, (Fig. 3,) which works into the large wheel M, mounted on the shaft N, upon which is fixed a large channelled barrel or drum *n*, (Figs. 1 and 4,) round which the hauling chain O, is coiled; this chain passes upwards through the hollow crane post, over the indented pulley P, to a double pulley fixed at the jib head, thence round the blocks R, to which the excavator is suspended, as the chain wound up draws the excavator out of the ground both in a forward and upward direction, when driven into the ground by the second motion. This last motion is communicated by the chain traversing over the indented pulley P, to another gearing. On the axle of the indented pulley P, is fixed a bevelled wheel *v*, (Fig. 2,) which works into a similar one *v'*, (Fig. 1,) mounted on to the upper end of the oblique shaft V, on the lower end of which is a corresponding bevelled wheel *v''*, working into another *w*, fixed upon the shaft W; upon this shaft is a pinion *w'*, which takes into the large spur wheel *u'*, mounted upon the shaft U, upon which is a channelled drum *u*, round which is coiled the chain *s*, attached to the diagonal wooden arms S; on the lower end of these arms is fixed an iron yoke, to which is suspended on pivots the excavator. By this arrangement, as the main chain O, passes over the pulley P, motion is communicated to the shaft U, for the purpose of forcing downwards in a diagonal direction the arms S, and with them the excavator into the ground. A man stands upon the stage *f*, for throwing in and out of gear this apparatus, and to regulate the motion for lowering or raising the excavator.

The next motion to be described, is for the purpose of turning the crane round either to the right or to the left; this is effected by another gearing in the following manner. On the first crank shaft L, is fixed a bevelled wheel *l'*, (Fig. 3,) which works into a similar wheel *g*, mounted on to the end of a horizontal shaft G, upon which are placed loose two bevelled wheels *g' g''*, either of which can be thrown in or our of gear so as to work, as may be required, into the large bevelled wheel *h*, mounted upon the shaft H; upon this shaft is a pinion *h'*, which works into the wheel *j*, fixed on the shaft J, upon this shaft is fixed an indented pulley *j'*, round which the chain *r*, is coiled, and passes upwards over pulleys *s*, round either side of the horse shoe pulley, to the ends of which it is fixed by iron bolts; the horse shoe pulley is fixed by means of strong iron stays to the crane, and when it is made to revolve the crane jib is turned round on the stationary post *t*, either to the right or to the left as may be required, and empties the contents of the excavator into a wagon or barrow.

The Progressing Motion is effected by placing on the hind wheel axle a strong wheel, shown by a dotted circle *b*, (Fig. 1,) which communicates with a pinion *b'*, on the shaft *i*, by an intermediate pinion *b''*, as shown by a dotted circle; motion being given to the shaft H, by the bevel gearing, described in the last motion, a forward or backward motion of the machine is obtained.

We have no precise data as to the cost of the machine or the quantity of work that can be performed by it, further than a short paragraph we gave in the last November number of the *Journal*, wherein it states that the machine is capable of digging 1000 cubic yards of earth *per day*, and that a machine complete costs about 6000 dollars in America.

ROOF OF THE RIDING SCHOOL AT NEWCASTLE-ON-TYNE.

(With an Engraving; see Plate VI.)

Sir—Having expressed your intention of giving some examples of construction useful to the student, in the description of the roof of the Polytechnic Institution, Vienna, in a former number of your excellent work, I am induced to send you the enclosed sketch, on account of the similarity of construction in the two, and they being the only cases I know extant where support is obtained from the side walls of the building on a line lower than the level of the tie beam, I shall first describe the peculiarities of the Vienna roof, and then of the roof at Newcastle. The former is 56 ft. span, and formed of curvilinear ribs 12 in. square, standing on a set-off of the wall considerably below the wall plate, and the crown of the rib rising about as much again above it, the slope or pitch of the roof being made uniform with rafters of smaller scantling. The ribs are cut out to the sweep of the curve, and are not laminar ribs, by which mode much additional stiffness is acquired. It is evident the arch is the principle of construction. The covering is copper, the weight being about 100 lb. per square, whilst tiles are 650 lb. weight per square. The annexed engraving exhibits the roof constructed over the circus or riding school at Newcastle, erected in 1789, under the superintendence of Mr. David Stephenson, architect, who was a resident and practised in Newcastle; he was the architect of the Theatre Royal and All Saints' Church, and architect to His Grace the Duke of Northumberland, &c. The span of the roof is 64 feet in clear of the walls, the length about 76 ft., and the height of the room from the floor to the crown of the arch, or horizonal beam at the foot of king post, 30 ft. The tie beams and principals are 12 ft. by 6 ft. placed 10½ ft. apart. The struts from king post 8 ft. by 8 ft.

The king post, straining collar (the horizontal beam) and struts from side walls, 12 ft. by 10 ft. in two thicknesses and bolted together. The purlins are 10 ft. by 6 ft. and about 9 ft. apart, being four in number on each side of the span. The common rafters are 5 ft. by 2 in. and are placed 3 ft. apart from centre to centre. The ridge 12 in. by 2 in.

By a comparison of the two roofs, the simplicity of the Newcastle roof over that with curved ribs, is at once apparent; no wall plates are used at the foot of the struts on the side walls, and at the level of the eaves; a pole plate and vertical posts at the foot of each rafter is dispensed with. The braces are prolonged to the king post, and act both as a tie beam and a counter strut to the main struts or portion of the curb roof, resting on the side walls at a level lower than the eaves. The principle of this roof is that of the common curb roof, as by inspection of the sketch it will be seen that the strongest scantlings are so arranged. On a few of the couples or pairs of principals a curved rib is affixed to the tie beam and strut, so as to give the roof a curvilinear form; but as it is dispensed with in some, it shows that it is not essential to the stability of the structure.

I am, Sir,
St. Ann's, Newcastle-on-Tyne. Your obedient servant,
O. T.

ON REVERSING LOCOMOTIVE ENGINES.

(With an Engraving, see Plate VI.)

Sir—Having by chance fallen in with a number of your *Journal*, (the number for February, 1842,) I perceive in it a design for reversing locomotive engines, signed H. and P., upon which, with your permission, I beg to make a few remarks, as the principle of it is similar to one of my own.

In the latter part of the year 1842, I designed two plans for reversing, the reversing valve being in the one case a slide, and in the other a four way cock; the former of these was published in a contemporary journal,[1] but having been forestalled in my design for the latter, it was never published: the two grand objections to be contended against in these designs, were, the pressure of the steam against the under side of the slide when reversed, and the (as yet) impossibility of obtaining *double lead*; to obviate the former of these, I proposed the design enclosed, which is much more simple and less complex than H. and P.'s plan. In the first place, the use of the four way cock for changing the direction of the steam, does away with the necessity of filling up the smoke box with the piston valve, and is besides, less expensive; secondly, the connexions between the pistons in the *working* valve box, are mere rods, instead of the pipes used by H. and P.; thirdly, a less quantity of steam pipes are required, as instead of *two* sets of pipes between the reversing and working valves, I use three short pipes crossing the bottom of the smoke box, connecting the *centre* of each box, and the *ends* individually.

For explanation of my design, allow me to refer you to the sketches enclosed.—See plate VI.

A, is the steam pipe, which conveys the steam from the top of the dome H, through the top of the smoke box, to the four way cock B, from whence the pipes C and D, take it to the valve boxes, the pipe C, connects the cock with the *ends* of each valve box, or that part on the *outside* of the working pistons in it, and the pipe D, connects it with the centres of each box or that part of the box *between* the pistons, in Fig. 1; the four way cock (shown in section) is so set as to allow the steam to proceed along the pipe D, to the *centres* of the valve boxes, while the waste escapes up the pipe C, from the *ends* of them, into the blast pipe; there are three pipes between the valve boxes E E, one of which is shown at F; the section of the valve box in Fig. 2, shows the positions of these pipes, which enter the box at K, K, K', the pipe D, being connected to the box opposite K', and thence proceeding across to the other box, and the pipe C, being connected opposite to the passages K K, and thence crossing to the box on this side; the mode of action of the valve is so simple, as not to require any explanation further than that the pressure is balanced as effectually, as in H. and P.'s plan: the dotted lines show the position of the four way cock plug when reversed. Having, as I hope, fully described by own plan, will you allow me to say a few words respecting H. and P.'s mode of obtaining *double lead*, may I ask them if this plan has ever been tried, and if so, if it was found to answer the inventors' expectations, as it is my firm belief, that if it had been tried before its appearance in your pages, it never would have made that appearance. The mode of working two valves with one eccentric, is an exceedingly ingenious one, and as far as I am aware, is quite an original idea; but it will not require much demonstration to show the futility of the mode of obtaining lead, by the use of the circular slots; the mistake into which H. and P. seem to have fallen, is by no means a solitary instance of premature conclusions, as witness the propositions contained in the 3rd and 4th Vols. London *Mechanic's Magazine*. I will take the same position of the eccentric, as given by H. and P., thus in Fig. 3, let the perpendicular dotted line represent the position of the crank, being at half stroke, then (lead being given) the position of the pin on the lever for working the valve, will be at D; but suppose the steam passages to be reversed, the crank, carrying with it the eccentric ring, will revolve in a contrary direction, and the pin D, will not be moved until the crank arrives at C, as shown in Fig. 4, consequently the valve will be just so much in arrear as it had lead in the former position, as the valve lever will not be in the proper position for giving lead until the crank arrives at C, whereas it ought to be in the same position as in Fig. 3, which is at half stroke. It is not, perhaps, generally understood, that the real position of the valve to obtain lead requires *no alteration*, when reversed in this manner, but the relative position of the valve to the motion of the eccentric must be altered.

I am, yours, obediently,
12, *Great Avenham Street, Preston,* William Johnson.
April 7, 1843.

[1] The Practical Mechanic and Engineer's Magazine.

VELOCITY OF WATER DOWN VERTICAL PIPES.

Sir—I have attentively perused the several articles which have lately appeared in your scientific *Journal*, on the velocity of water down vertical pipes under certain conditions; but I by no means agree with your correspondent T. F....n, who asserts, that the velocity of water down a vertical pipe 16 feet long, under these conditions, will be 32 feet per second. Nor does it appear to me, that the mutual cohesion between the several layers or particles of water in the pipe, is a force sufficient of itself, to account for the solidity of the issuing stream, as stated in a late number of your *Journal*.—The following is my humble opinion on this interesting subject.—

First, as to the *velocity* of water down a vertical pipe 16 feet long the top of the pipe being considered to be always covered with water.—

The following table extracted from "Grier's Mechanic's Dictionary," exhibits the natural velocity due to a body, after having fallen through the undermentioned distances: and will be found useful as a reference in the following remarks.—

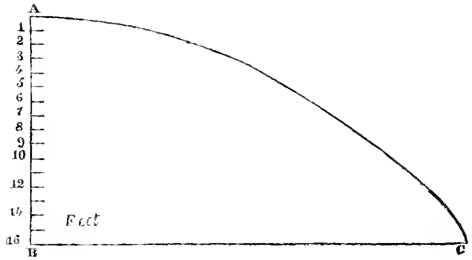
Space through which the body falls in feet.	Velocity acquired at the end of the time. feet per second.	Space through which the body falls in feet.	Velocity acquired at the end of the time. feet per second.
1	7·3103	10	24·7617
2	11·0637	11	25·9628
3	13·4165	12	27·1232
4	15·6562	13	28·2264
5	17·2903	14	29·9786
6	19·1725	15	30·3601
7	20·7078	16	31·3176
8	32·1435	17	32·2833
9	23·4890	18	33·1975

It appears from this table, which is founded on the well-known law, that "the velocity acquired by a body falling from rest in a free space, is as the square root of the space fallen through," that the velocity of water at the end of the 1st ft. is 7·3103 ft. per second, (and not 4 ft. as stated by your correspondent T. F....n); at the end of the 4th ft. it is 15·6562: and at the 16th ft. 31·3176 ft. per second: or, in round numbers, 8, 16, and 32 ft. per second. If then the motion of the whole of this column is uniform, whence has the power been obtained to increase the velocity of water at the end of the first foot, from 8 feet per second, to, say, 16 or 32 feet per second? Doubtless from the superior velocity due to the lower parts of the water in the pipe. If this is the case, then must the natural velocity due to the lower portions of the water be diminished; for nobody when in motion can impart any motion to another body at rest, or increase the velocity of that body if in motion, without a diminution of its own velocity, in proportion to the respective momenta of the two bodies.—Therefore, it is not possible that the water at the end of the 16 feet pipe, whose natural velocity is 32 feet per second, can, after it has imparted a quicker motion to the higher portions of water, still possess the same velocity that it would have had, if it had not parted with a portion of that velocity, in increasing the velocity of the upper parts of this column. Consequently, it follows, that the velocity of the water issuing from the pipe must, (if the stream fills the pipe and flows uniformly through it), be diminished, and therefore be less than 32 feet per second.

Next, as to the cause of the *solidity* of the issuing stream.—Let us first consider the phenomena of a stream of any liquids falling from a height, but not down the interior of a pipe; or even a continuous stream of leaden bullets. For a short distance we perceive the stream solid, till the increased velocity of the lower parts as they descend causes them to leave those immediately above them, air filling up the intervening space, and thus the solidity of the stream is broken. Now let us turn to the pipe, and we see, by the above table, that the natural velocity of a layer of water which has fallen one foot, is 7·3103 feet per second, and of another which has fallen two feet, 11·0637 feet per second; why then does not this lower portion fall faster than the higher one, and separate from it, and thus break the solidity of the stream? Simply because if it did so, there would be a vacuum between these two portions of water, bacause the sides of the pipe are impervious to the air; and as the atmosphere is pressing on the water at the top and bottom of the pipe with a pressure, say, of 14 pounds per square inch, these portions are kept together by this pressure; for no sooner does an under stratum of water try, as it were, to leave the stratum above it, and form a vacuum, than the presure of the atmosphere at the top of the pipe is brought into action, and the velceity of the upper stratum increased; while at the same time a portion of the atmospheric pressure, being by the same tendency removed from the upper surface of the lower stratum, the full pressure of the atmosphere is exerted upwards at the base, and the velocity of this lower stratum is consequently diminished. This certainly appears to account more satisfactorily for the solidity of the stream, than the force of cohesion; for this force must have the same influence over the particles of water whether they are in the inside or on the outside of the pipe.—As a proof, that when water is descending in the interior of a pipe, which is continually covered with water on the top, the atmosphere has a tendency to rush in through the sides. I need only mention the wellknown fact, that if in a pipe under these circumstances there happen to be a crack, or a hole bored through the sides, the air immediately rushes in, and the solidity of the stream is destroyed.

Lastly, to determine the *actual velocity* of this continuous column of water.—Let us suppose the water in the pipe composed of an immense number of laminæ, each of the thickness of a particle or atom of water, and consequently of the same thickness and weight; and let us take under our consideration the case of any two of these contiguous laminæ, and suppose that the velocity due to the higher one is, say, one inch per second; and the velocity due to the lower one is, say, two inches per second. Then if these two laminæ, when moving with these velocities, be at the same instant connected by the pressure of the atmosphere, or otherwise, so that the one cannot move on without the others moving along with it, it is evident, since the quantity of matter in each is the same, that the resultant velocity of the two will be one half of the sum of their original velocities, or one and a half inches per second. If then we could obtain the natural velocities due to each respective laminæ, the average would be the result and velocity for the whole column. On taking the average of initial and final velocities due to the water at the end of each successive two feet, from the foregoing table, and then dividing their sum by 8, we have 20·6077 feet as the average velocity of the whole column. And if by approximating rather more closely to the system of atomic laminæ, we take the average of the initial and final velocities due to each *foot* of water, and divide the sum by 16, the resultant is 20·7265 feet per second.

Again, since "The velocity acquired by a body falling from rest in free space is as the square-root of the space fallen through," the space varies as the square of the velocity.—If then, we take the spaces fallen through at the termination of each foot in the 16 feet, (as in the first column of the above table) as abscissa, and the respective velocities (as in the second column) as ordinates, the resultant curve will be a parabola similar to the figure below.—



Let us suppose the line AB, represented in this figure 16 feet, or the space fallen through, to be divided into an almost infinite number of parts equal to the number of atomic laminæ in the column of water; then if we could find the length of the several ordinates at those points, and divide the length of the whole by their sum, the result would be the average length of all the ordinates, and consequently the average velocity. This can be done by finding a rectangle whose area is equal to the area of the parabola, and one of whose sides is equal to AB.—Now, $\frac{2}{3}$ × abscissa AB × ordinate BC = area of the parabola = $\frac{2}{3} \times 16 \times 31{\cdot}3176 = 334{\cdot}0544$ ft. Therefore $\frac{334{\cdot}0544}{16} = \frac{\frac{2}{3} \times 16 \times 31{\cdot}3176}{16} = 20{\cdot}8784$; consequently the two sides of this rectangle are 16 feet and 20·8784 feet, of which 16 feet represents the space fallen through and 20·8784 feet the average of all the ordinates, and consequently the average velocity. 20·8784 feet therefore is the average of the natural velocities due to the several atomic laminæ composing this column of water. Again, it is evident, that since the abscissa AB (or 16 feet), enters both into the numerator and denominator of the fraction representing the average velocity, it may be eliminated altogether; and the expression then becomes $\frac{2}{3} \times 31{\cdot}3176$; or, "The velocity of water descending the interior of a pipe 16 feet long, is equal to $\frac{2}{3}$ of the natural velocity due to a body, after it has fallen through a distance, in free space, equal to the length of the pipe."

I. T——N.

Shropshire Lunatic Asylum.—We understand Messrs. Cooper, builders, of this town, have entered into contract with the magistrates of the county of Salop, for the erection of a Lunatic Asylum for that county. The building is from a design by Messrs. Scott and Moffatt, of London, in the Elizabethan style. The extent of the front 280 feet, and arching 170 feet. The plan is in the shape of the letter H. The first part of the building will cost £11,000.—*Derby Reporter*.

THE AERIAL TRANSIT MACHINE.

Analysis of the projected Aerial Transit Machine, and of the principles involved in its construction and employment.

FROM the earliest period of antiquity the desire to navigate the skies has ever formed one of the most prominent passions of the human breast. In the commencement, ere man had acquired sufficient skill to be able to submit his ideas to the test of experiment, the indulgence of this passion could only display itself in vain aspirations or the wild effusions of an unrestrained and romantic imagination. To this source may be traced some of the most elaborate conceptions of the Heathen poets; the fables of Dædalus and Icarus, of Perseus and Bellerophon, the air-borne car of Medea, the winged heel of Mercury, the Harpy, Chimæra, Pegasus, and many others equally fanciful and absurd, which characterise the history and mythology of the remoter ages.

As the world, however, advanced, and some insight began to be obtained into the nature and constitution of the surrounding atmosphere, the reveries of the poet gradually gave way to those of the philosopher, and men at length bethought themselves of imitating what, before, they had been contented to admire. Thenceforward to the present period, all that human ingenuity could devise, has been constantly arrayed in the pursuit of this favourite object, and the empire of the skies has never ceased to be contested with an energy and zeal almost as great as ever was displayed in the subjugation of the earth.

Of the schemes to which this interesting inquiry has given rise, some, and those among the earliest, professed to operate after the manner of birds, by the mechanical reaction of wings against the subjacent air. Such was the nature of the plans of Roger Bacon, Fleyder, and others, too numerous to mention, some of whom attested the insufficiency of their devices at the expense of their limbs, and even of their lives, while some, more cautious, only projected experiments, which they left to others to perform.

To schemes of this description, which may be termed the *mechanical*, succeeded others based upon the physical or chemical principles of the atmosphere, real or presumed. Of this nature were the designs of Bishop Wilkins, and the Jesuit Lana, and that (more absurd than either) which, proceeding upon the supposition that the particles constituting the upper strata of the ætherial mass were of a more buoyant consistency than those below them, proposed to accomplish its object by enclosing in a proper vessel a portion of air abstracted from the very regions which itself was to offer the only means of approaching.

It would occupy more space than we could here afford, and serve moreover no beneficial purpose, were we to attempt to recount, much less to describe, all the schemes that have been successively proposed, dilated upon, tried, found wanting, and subsequently abandoned, in the prosecution of this interesting design. Suffice it to say that in the one material point, namely, the procuring an elevation into the bosom of the air, they all proved equally inefficacious, until the discovery of the balloon by the brothers Montgolfier in the year 1782. Two instances, indeed, and but two, are authentically recorded, in which the attempt to fly by mechanical means has been attended with partial success—that of the Marquis de Bacqueville, who, in the year 1742, accomplished a flight partly across the Seine in Paris, and that of an individual of the name of Degen, who, at Vienna, some years ago, succeeded in raising himself to a height of about 50 feet by means of the alternate reaction of large surfaces shaped after the fashion of an umbrella, and worked by the exercise of the arms and legs. These, however, were but the more splendid failures; and the prospects of aerial navigation may be said to have been at the very lowest ebb when the ingenious discovery of M. M. Montgolfier, with the subsequent improvements of M. Charles, in which hydrogen gas was made to take the place of heated air, revived the drooping spirit of enterprise with the promise of a more easy triumph in the fields of air. Abandoning the former mode of operating for the purpose of obtaining an ascent, men now directed their attention entirely to the means of controlling the motions of the machine, by the intervention of which that, apparently the most arduous and perplexing condition of atmospheric transport, had been so suddenly and unexpectedly accomplished.

In this, however, as in the more independent processes of flight by mere mechanical reaction, human ingenuity was doomed to be defeated. With all the flattering prospects of success which an almost unlimited power of support appeared to hold out, not only was there no commensurate progress in the essential object of securing a definite direction, but even greater difficulties appeared upon further acquaintance to stand in the way of aerial guidance by means of the balloon, than were apprehended, before that instrument had brought men into a more practical acquaintance with the character and conditions of the element with which they had to contend. The magnitude of the forces developed, owing to the necessary bulk of the machine, seemed to deride all attempts at control, while at the same time the expenses attending its construction and employment, imposed a limitation upon the experiments, by means of which alone these obstacles could be expected, if ever, to be overcome. Under these accumulated and, perhaps, insurmountable difficulties, the balloon gradually ceased to be regarded as an object of scientific interest, and at length shared the fate of all other discarded favourites, in a neglect as inconsiderate as it had formerly been courted and admired.

After a period of excitement, a state of lethargy is no uncommon result; and accordingly when the first burst of admiration and wonderment had subsided, and a succession of failures had begun to characterise the new art with something like a tinge of absurdity, the public gradually settled down into a condition of apathy and disregard in respect of aerial navigation, even the more profound from the greatness of the disappointment to which they had so recently been subjected. Occasionally, indeed, the rumour of some new improvement in the art of "flying made easy," more plausible or presumptuous than the rest, would startle them from their propriety, and, for a while overcoming their antipathy to the balloon, awaken a languid spirit of speculation, in which the dread of disappointment could plainly be seen predominating over the feebler expectations of success. These, however, were but temporary excitements, which died away as soon as they were felt, and the subject appeared to have been almost entirely forgotten, except by a few of the most ardent cultivators of the art, when the announcement of a *really new* project, totally unlike any that had gone before, and repudiating all connexion with the obnoxious instrument by which they had been so often before deluded, has again roused all their sympathies, and produced a fever of expectation which a month of cool reflection has not yet been able to allay.

The first communication of this project in a tangible form, having taken place since the publication of our last number,[1] we were precluded from giving it that notice at the time which we would otherwise have bestowed upon it; not only as in itself meriting investigation, but in consideration of the intense interest and divided opinions it had certainly excited throughout no small nor uneducated portion of the community. Ushered in with a somewhat more than ordinary degree of pretension, backed by reference to experiments of a most flattering description with models, and, to crown all, stamped, as it were, with the authority of a bill in Parliament, it not only justifies but imperatively calls for an inquiry which, to be available, must be equally searching and exact. It is of no use to regard a scheme of such complicated contrivance and involving such recondite principles, in a superficial manner or in a general point of view. The mere fact of a principle being correct is no proof of the practicability of a scheme which is founded upon it; and if the success of a *model* were conclusive in respect of the object it is intended to represent, neither would Mr. Cocking have perished in the descent with his parachute, nor would this very question of aerial navigation have remained undetermined to the present day.[2] In fact the working of

[1] The public were first made acquainted with the details of Mr Henson's patent through the plans and descriptions which appeared in the weekly journals of that rather ominous date, the 1st of April.

[2] It is well known that Mr. Cocking had spent upwards of 20 years in framing and improving models of the machine in which he afterwards lost

a model determines nothing that cannot as well be determined without it—the correctness of the principle, which is the proper subject of mathematical research. With regard to the possibility of its construction upon the great scale it would determine nothing, even if it were, which in this case it is absolutely impossible it should be, in the strict sense of the word, a perfect model, observing all the proportions of strength, weight, bulk, power and dimensions as they will appear in the real machine with reference to which they are contrived. The only true and satisfactory mode of arriving at any thing like a correct conclusion respecting the efficiency of the machine in question, or any other of the like character, is by a critical examination of its parts severally and with reference to each other, which is the course we intend to pursue on the present occasion. To enable us to do this the more intelligibly, we will begin by describing in a few words what Mr. Henson's machine is, and what is the principle upon which it is intended to act, so far as they can be collected from the statements in the public press. In general terms, then, Mr. Henson's machine may be described as an horizontally extended plane, 150 feet in length and 30 in breadth, (consequently containing an area of 4,500 square feet) across which, close beneath and in the centre, is suspended a cuneiform car or body accommodated with a pair of circular flying vanes, by the oblique impact of which against the air (upon the principle of the archimedean screw) it is designed to be propelled, and furnished with two caudal appendages like fans, one of a large and the other of small dimensions, by means of which the vertical and horizontal course of the machine is intended to be controlled. The whole is proposed to be set in motion by an accession of extraneous force acquired through the intervention of a preliminary descent down an inclined plane, and maintained by the operation of a steam-engine located in the body or car of the machine. Omitting therefore the consideration of minor details, our attention will be directed, in succession, to the suspending plane—the caudal appendages—the flying vanes—the motive power—and, finally, to the principle upon which the elevation in the first instance is intended to be secured.

And, first, with regard to the suspending plane. The object of this contrivance, involving, in fact, the essence of Mr. Henson's patent,[3] is, simply, to obtain a *direction* for a certain amount of weight different from what it would assume if left to pursue its course according to the unobstructed force of gravitation. This it accomplishes, or would accomplish if efficiently constructed, by a progressive motion conferred upon it at an angle inclined to the horizon, whereby a part of the force generated by its opposition becomes resolved in a direction opposed to its descent; and the merit of it consists in this,—that a less degree of force is required to produce this progressive motion than that which the actual weight of the machine would require for its support. A familiar mode of illustrating this has been adopted by Sir George Cayley, in the *Mechanic's Magazine* for the first of April. It proceeds upon an analogy with the suspension of spherical substances upon an inclined plane, and cannot be better explained, as far as it goes, than in his own words. "Suppose A B to represent an inclined plane,

rising one foot in ten; it is well known that if the ball F weighed 100lb., a force of 10lb. applied horizontally would sustain it from rolling back. Conceive the same line A B to represent, also, the section of a large surface, like the sail of a ship, and that C G represents a cord by which it is sustained from being driven back by a horizontal wind in the adverse direction. If the sail contains 100 square feet of surface, and the wind has sufficient power to press with one pound to the foot, 100lb. weight will be supported, and the tension on the cord will be only 10lb. It is the same thing whether the wind thus blows against the sail, or the sail be driven with equal velocity horizontally in calm air; the 10lb. propelling power will still sustain the 100lb. in the air." It only remains to observe in what manner it effects this; namely, by producing such a rate of motion in the inclined plane as, at the given angle, would generate a pressure of one pound to the square foot.

Now to apply this to the case of Mr. Henson's machine. In the first place, the area being 4500 square feet, and the weight (taking it according to the statements in the public prints) being 3000lb. supposing the same angle of inclination to be observed as in the foregoing illustration (that is to say, one in ten) if the wind move at a rate sufficient to generate a pressure equal to two-thirds of a pound upon the square foot, the resistance to its horizontal progress, and consequently the force it would require to compete with that resistance, would be one-tenth of its actual weight, or 300lb. If, instead of an angle of inclination of one in ten, be substituted an inclination of one in twenty (which is perhaps more nearly in the ratio observed by birds in their flight, and consequently more consistent with the analogy Mr. Henson appears most desirous of maintaining) the same result will be obtained with half the force, or a resistance of 150lb.; and accordingly it is upon this hypothesis that we shall proceed, in the next place, to investigate the rate at which the machine must be propelled in order to enable it to realize this resistance.

The proposition which we here have to deal with is simply, "having the pressure upon a plane surface at a given angle of inclination, to find the *rate* under which that pressure is developed;" and the solution is deduced from a consideration of the rate corresponding to the resistance the same plane would experience if perpendicularly impinged upon.

We will not trouble our readers with entering into the details of the equations by which the ratio of the forces generated by inclined planes moving in fluid media has been determined; but, content with referring them for the solution of these interesting problems to Whewell's Treatise upon Dynamics (or indeed any other works of good repute upon the same subject), proceed at once to observe that the resistance experienced by an inclined plane in passing through the air with a given velocity, varies as the cube of the sine of the angle of impact; and that, consequently, whatever be the ratio which this number bears to the cube of radius (the sine of the angle of 90 degrees), the same will be the ratio of the resistance it will experience at the angle assumed, to that which it would experience at the same rate of motion if perpendicularly encountered.

Now the velocity under which the plane in question, containing an area of 4500 square feet, would develop the prescribed amount of resistance, namely 3000 lb. by perpendicular impact (being at the rate of two-thirds of a pound per square foot) is, according to the tables of Messrs. Rouse and Smeaton, founded upon actual experiment, about 12 miles an hour. The angle of inclination at which we have agreed to dispose the suspending plane, being one in twenty, may be considered with sufficient accuracy for practical purposes, as an angle of 3 degrees, the sine of which (radius being estimated at 1) is ·05 As therefore $1^3 = 1 : {\cdot}05^3 = {\cdot}000125 :: 3000 : .375 =$ the resistance on the inclined plane at the rate of 12 miles an hour; and the resistance increasing as the squares of the velocities and consequently the velocities following the ratio of the square roots of the resistance, as $\sqrt{{\cdot}375} = {\cdot}6 : \sqrt{3000} = 55 :: 12 : 1100$, the number of miles per hour representing the rate of the inclined plane required to support it, in conformity with the conditions described.

The consideration of some of these conditions will, however, show that this rate of motion, and, consequently, the amount of force by which we have presumed it to be generated, is far from sufficient to

his line; and the public will not yet have forgotten the pleasing experiments with Mr. Green's model of the balloon at the Polytechnic Institution last year, in which the practicability of controlling its course by mechanical reaction was so interestingly illustrated.

[3] It is not our desire to detract from the merits of any individual who seeks by his ingenuity to extend the limits of our attainments in art or science: but a regard to truth obliges us to observe that the idea of obtaining an ascension by means of the inclined plane is not original or peculiar to Mr. Henson's project; being in fact the mode to which all those who of late years have thought to effectuate an aerial navigation by mere mechanical reaction, have looked for the solution of this interesting question. In the number of the *Mechanic's Magazine*, for the 25th April, 1829, is a sketch of an apparatus constructed entirely upon the same principle, and many more might be referred to of an earlier as well as a more modern date.

satisfy the exigencies of the case. In the first place, the data upon which the calculations of the resistance of the atmosphere have been grounded, are deduced from a consideration of the density under little more than mean pressure, equivalent to the support of a column of mercury 30 inches in height; whereas it is well known that it frequently, or at all events occasionally, falls to an extent of nearly two inches, implying a reduction in the density equal to $\frac{1}{15}$th of its whole amount. In respect of this condition alone, therefore, 25 miles per hour would have to be added to the above to enable the machine to maintain its pristine elevation, *but slightly removed above the surface of the earth.* But the mere retention of this elevation, without the power of augmenting it at will, within certain limits, would be evidently very insufficient for the purposes of a perfect aerial navigation. It is unnecessary to dwell upon the many occasions which the inequalities of the earth's surface would present, in the extancy of the objects upon it, both natural and artificial, when it would be necessary to assume a higher course in order to escape a collision. Some of these, it is true, could be *gone round*, and thus avoided, instead of being surmounted. But there is still a great variation in the prominence or altitude of the plains and large ranges of mountain country, which could not be so dealt with; and in respect of these, a considerable allowance must be made in the powers of the machine. No part, for instance, of the Alps or Pyrenees, extending entirely across Europe, could be traversed under an elevation of 8000 feet, and without the power of accomplishing this, the use of the machine would be restricted to a very small portion of our own continent, or forced to make a *detour* equal in some cases to perhaps the entire extent of its intended route. Now for every 1200 feet of elevation, in the beginning of the scale, a reduction of one inch may be counted upon in the height of the barometrical column; so that if we only presume an elevation of 8000 feet, we shall have imposed upon the aerial machine an obligation of conducting her operations in an atmosphere the density of which will have been reduced to an extent indicated by a fall of the barometer to 23 inches; from which, if we further subtract the amount of the variation from mean pressure previously mentioned, we shall have a density of the medium only three-fourths of that, upon the hypothesis of which her former velocity had been assigned. Now the pressure, according to the first law of resistances, being directly as the densities of the media, by this condition, therefore, we shall have incurred a fresh obligation of speed, following the ratio of the square roots of the densities, the total amount of which will be determined by the rule of three proportion; thus, as $\sqrt{3} : \sqrt{4} :: 1100 =$ the number of miles per hour necessary to accomplish the required resistance under mean pressure : 1246 miles (nearly), = the rate at which the machine must be impelled to enable it to effectuate the same amount of resistance under the reduced pressure to which, in its elevation, we have seen it will have to be exposed. And this augmented velocity, be it observed, arising solely out of the reduction in the density of the medium, will be maintainable by the application of the same effectual force, namely 150lb., by which the first assigned velocity was shown to be determined.

Hitherto we have regarded the qualifications of the machine in respect of rate and force apart from any considerations but the necessity of securing an elevation in the air. But a velocity of 50 miles an hour, however it might satisfy the conditions of support, would evidently be insufficient to realize that progress independent of the action of the winds which is necessary to the constitution of a *certain* and *serviceable* mode of transport. For this purpose, something more than the actual rate of the winds is the least amount of speed which could be considered sufficient to meet the exigencies of the case. Now, the average rate of the winds, in this climate at least, may be stated to be about 25 miles an hour. This we are enabled to determine, not from the observations of the meteorologist alone, but also, (and what is more to the point because founded upon experience in that part of the atmosphere with which we have more especially to do) from a consideration of the average rate of Mr. Green's aerial excursions,[a] deduced from a series of 249 voyages, executed generally, of course, in the most favourable periods of the year. From this we learn that 25 miles an hour is the mean rate at which a body floating in the air may expect to be transported; to this we must add considerably more to secure a balance in favour of the machine, for which an additional amount of force must be provided over the amount assigned for its support.

The determination of this new quantity however depends entirely upon data with which we have not been furnished. In the calculations which we have hitherto made, we have regarded the machine as a mathematical plane, altogether unproductive of any resistance except what contributes to the counteraction of its descent. This, however, it is scarcely necessary to observe, is an hypothesis which is not correct in fact; and the distinction will be seen to be of serious importance, when we consider that, for every square foot of plane surface made up of all parts and projections that receive the direct impact of the air, the machine experiences, at the rate of 100 miles an hour, a resistance equal to about 50 lb.; so that if we only suppose it to present an additional extent of resisting surface equivalent to a plane of 10 square feet, it will encounter an opposition equal to four times what has already been assigned to it, and consequently involve a necessity for four times the amount of force which was previously required.

Now the conditions of *force* in the first instance prescribed might have been considerably (almost indeed, indefinitely) reduced by increasing the superficial contents of the suspending plane. For instance, if instead of an area of 4500 square feet, it had presented a surface of double the extent, (which it could have been made to do, by doubling the breadth or adopting another form, without augmenting the difficulties of construction,) the same degree of elevation would have been obtained with less than half the force; as will be evident if we consider that while the resistance follows the ratio of the dimensions, the dimensions observe the ratio of the squares of the velocities: so that in this point of view the suspending plane of Mr. Henson's machine may be shown to be contrived without due regard to the economy of the forces by which it is upheld.

But there is another purpose which the suspending plane is required to fulfil, and which must be taken into consideration in adjudicating upon the plan before us. It is to be recollected that this elevation is maintained only by the exercise of a progressive motion, and that in order to effectuate a safe descent this motion must be suspended. It is scarcely necessary to observe that a projectile force, however modified it might be, is quite incompatible with the preservation of human life under any mode of accomplishing a descent which could be proposed; and that unless it can be accomplished by the independent resistance of the suspending plane, it can never be safely accomplished at all. There are two modes by which the actual rate of descent may indifferently be ascertained. To one of these modes, which is an inference from the pressure exerted by the air in motion at different degrees of velocity, we have already adverted in determining the speed at which, under perpendicular pressure, the plane in question would generate a resistance equal to its weight. From this we have seen that a rate of 12 miles an hour is exactly answerable to the conditions of the case; being that at which a plane surface develops the resistance assignable to Mr. Henson's machine, namely, two thirds of a pound to the square foot; and accordingly that number expresses the rate at which the machine in question would descend through the air if left of itself to fall.

In addition to this method, Dr. Hutton has left us a formula by which the same may be calculated with sufficient accuracy for practical purposes, and which it will be seen leads to a result confirmative of the approximate correctness of our conclusions. Taking W to represent the weight and D the diameter of a circular plane of the given area, $\frac{26}{D}\sqrt{W}$ gives the number of

[a] "The total distance which Mr Green accomplished in the course of his first 200 aerial excursions, a very accurate computation enables him to fix at 6000 miles; and the time consumed in the performance at 240 hours. The former of these two quantities divided by the latter gives the result above." *Aeronautica*, page 298.

feet per second which constitutes the terminal velocity of the falling body. In the present case, D being equal to 76 feet and the weight 3000 lb., we have $\frac{26}{76}\sqrt{3000} = \frac{26}{76} \times 55 = 19$ feet nearly in a second, or somewhat less than 13 miles an hour. It is unnecessary to point out the insufficiency of this retardation to effectuate the safe descent of human beings. It will serve to give some idea of the force and necessary consequence of such a precipitation, merely to suggest the shock that would be experienced by an individual if he were to be launched unprotectedly against a solid wall from the top of a vehicle travelling continuously at the rate of 12 miles an hour. In this respect therefore, the suspending plane of Mr. Henson's machine is particularly deficient. It has been calculated, and no doubt upon good grounds, that the least rate of descent which consists with human safety is 3 miles an hour; and though if we could always command the conditions of the descent so as to alight upon our legs, we might be able to sustain a greater concussion without peril, yet, as a general principle, and more particularly with reference to the circumstances of the case before us, we shall not be too exigent in requiring a power of retarding the descent within double these limits. Now the resistance upon a square foot of plane surface in motion through the air at the rate of 6 miles an hour, is ·176 of a pound; and the whole weight to be sustained being 3000 lb., we shall have an apportionment of surface to weight in the ratio of about 6 feet to the pound; amounting in the aggregate to an area of 18,000 square feet, or 4 times the actual size of Mr. Henson's plane. The correctness of this estimate may be readily verified by reference to Dr. Hutton's formula before adduced, by which it will be seen, that such is the rate at which such a plane so loaded would make its descent through the air.

But for the continuation of these investigations we must refer the reader to our next number.

THE CAUSES WHICH HAVE ENNOBLED ARCHITECTURE.

By Frederick Lush, Associate of the Institute of British Architects.

An art which depends upon the cultivated powers of the human mind must be necessarily slow in arriving at perfection. As it had its origin in some simple want, its primary object is to satisfy the necessaries and promote the happiness of man, in whatever condition he may be placed. The end of architecture, like all other works of imagination and taste, is to give pleasure; but it will fail doing so, when this principle is lost sight of. On this account the expression of use and fitness has been considered by all writers on art, as the chief element of beauty: and we expect to find that the buildings of different nations will be indicative, not only of their peculiar habits and customs, but also of the country in which their several styles originated. There is no occasion to speculate on the influence which scenery and climate exert upon the mind, and how they consequently operate upon all the productions of man. The difference of opinion and degree in which the sentiment of the beautiful has unfolded itself in various parts of the globe, plainly shows that the temperature and circumstances of one clime are more congenial for the practice of this noble art than another. Nature scattered her beauties on the soil of the Greeks with a liberal hand, and as they were quick to discern and appreciate them, they were wrought by the sculptor on their temples and monuments. The embellishments with which they were thus supplied, were in harmony with surrounding objects; and we cease to wonder at the fascinating works which emanated from this favoured people, when we see that the finest models in nature were ever present to their imagination. Among these resources, none gave them, perhaps, greater power of conceiving what was beautiful, than the various passions, attitudes and proportions, which they had the opportunity of studying during the exercises of their athletæ. Here was exhibited to their astonished gaze the wonderful structure of the human frame; and it is when contemplating the character which man sustains in the varied scenes of life, when watching the many ways in which his hands are employed for advancing the good of his fellow-creatures, or, when he breathes and speaks to us out of the marble or canvass, that we recall to our memory the fine soliloquy of Hamlet: "What a piece of work is man! how noble in reason, how infinite in faculties! in form and moving, how express and admirable! in action, how like an angel! in apprehension, how like a god! the beauty of the world, the paragon of animals!" Who can deny then, that an anatomical knowledge of the human figure is the best education for the eye, and the basis of all grace and propriety in invention and design? The student needs to be reminded that his art will never be ennobled by only copying the orders of Vitruvius or Palladio. If the works of nature had not been their guide, the ancients had never attained to such perfection in architecture.

One of the most striking features in ancient art is grandeur. It was an object with the builders of antiquity to give great permanence to their works: a wish which sprung out of their natural love of glory and desire to appear great and enterprising in the eyes of posterity. An instance of the extravagance to which this passion carried them, is recorded in the tower of Babylon. Such a failure, however, occurring among men who were unguided by precedents and blinded to the consequence of their rash and presumptuous undertakings, would have the most beneficial results, and lead them to view the art of building *for eternity*, on more sound and philosophical principles. Curiosity has ever been busy in inquiring into the causes of things; and the most useful discoveries have arisen upon the errors of former ages. Michael Angelo had never, perhaps, raised a dome so triumphantly, if the attempt had not been made by others with less success before his time.

But although this sense of immortality is the first step towards a grand style, it depends likewise upon the goodness of the materials that are introduced, as it is these which give to buildings, whatever may be the purposes for which they are intended, all their character of strength and durability. Now, on these latter points, much of the fame of an architect rests, and for want of attention to them, we owe the ruin of many modern edifices: I allude to the one at Fonthill as an example most familiar to the reader. Every one remarks the great contrast between the size and dimensions of timber, for instance, used in buildings of a bygone age, with those of the present day: and the difference in their duration is equally great. The system of contract, which has been so prevalent of late years, and the heavy duty on materials of every kind, have operated powerfully in the change; and although in some cases the exorbitant proportions of strength observed in old houses seem to indicate an ignorance of the principles of construction, yet as they long outlast our feebler erections, and require force to raze them, we can scarcely blame what appears in some of their parts a want of geometrical skill. The architectural merits of our ancestors must be judged by the circumstances of the age in which they lived. They had doubtless been more sparing, and displayed more science in the use of their timbers, had they been less abundant; or had they been compelled, by the restraint of taxes, to make them answer their several ends with the least possible expenditure.

With regard to stone, we have no cause to complain of its deficiencies, or think lightly of the resources of our British quarries, although we have not the granite of Egypt or the marble of Pentelicus. Yet when we look on the dilapidated state of many of our edifices—when we think of the ruinous appearance of some of the colleges in the beautiful city of Oxford, the nurseries of so much profound learning and eminent piety, we have reason to lament the corrosive nature of the stones with which they have been constructed. In these latter, their rapid decay is owing to the broad surfaces of the laminæ or cleaving grain being presented to the action of the weather; and we see the result of placing them in a position contrary to that in which they lay in the quarry. One remedy for this evil would be the establishment of a society for testing the capabilities of stone and its fitness for durability, prevous to its being employed on public and national edifices.

On the other hand the mild and equable temperature of the east was favourable in effecting for the ancients that perpetuity at which they aimed; they did not suffer from frequent frosts and sudden changes; their beautiful statues were not injured by that quantity of coal-smoke which accumulates in our dense cities; nor did they see a Parthenon or Erectheium perishing in the lifetime of its founder. Instead of a few years altering the appearance of their temples, they remained as firm and perfect as ever after the lapse of centuries, and promised to be as lasting as the rocks out of which they were originally hewn. The immense size and weight, moreover, of the stones which their architecture demanded, contributed, independent of the cement, to the stability and breadth of the masses. And as the site of their cities was generally on the tops of lofty hills, it being the custom with idolatrous nations to offer sacrifice on such places, it is evident that to raise such huge blocks to the required height, betokened some degree of mechanical skill. Besides, when they knew the grandeur of effect which would be conferred on their buildings from an elevated position, and the advantages it would give them over invaders, they needed not a further stimulus to exertion: nor would they be slow in applying the principles of geometry to the carrying forward those great works. The Egyptians were unquestionably masters in this science. But their simplest and most effectual method in transporting their vast monoliths (as may be learned from one of their own paintings) was the use of rollers and the incline; in fact they would *skid* these obelisks, and by means of proper tackle, set them up just in the same way as modern labourers.

If we consider their cement, we find, as in the aqueducts, it presents a hardness that is impenetrable to water; and this through no less than 2000 years. The Romans and Greeks were particularly careful in the making of their mortar and in the use of it; with us, on the contrary, it is deemed a second rate consideration, especially in house-building, and is usually committed to the least instructed class of men. Allan Cunningham, in his life of Wren, speaking of St. Paul's, says:—"Though the stones are hewn with the greatest nicety, and the masonry seems all firm and compact, yet the mortar which should unite the whole into one solid mass, is in many places decayed and become as dust. This is the case even with some of those piers against which the public monuments are erected; when the outer line of stone is cut through, the mortar comes gushing through the aperture; the sand is sharp and good, but the lime, like too much of the lime used in London, has been deficient in strength." Notwithstanding this defect, every one who knows that the architect endeavoured to give permanence to his works and secure the praise of posterity, will be glad he is deaf to the voice of his biographer.

Of the religious edifices of the middle ages, there are some which retain, despite of time and tempest, so much of their original beauty, that most of their ornaments and rich carving seem as if they were the work but of yesterday. There are even preserved to us those curious devices with which the early sculptors were wont to decorate their handy works; and whether they alluded to the mysteries of their craft, or were emblematic of some moral truth, were yet always used to mark and identify a favourite subject. I regard their sacred architecture with feelings of reverence; for cold, indeed, must be the heart of that man who is insensible to the sublimity of the Gothic, when looking upon the roof at King's College, the Minster at York, or the magic groining and tracery of Henry VII's chapel. There is something so ennobling in this style, that it is peculiarly adapted to our Christian churches. It is easy to point out its claims upon our admiration. The Gothic architects, well knowing that devotion would be heightened by great size, loftiness, and durability, preserved all these characteristics of grandeur; and it is when surrounded by them, we are impressed with the religion of the place, and feel that we are in a building dedicated to the worship of Jehovah. Everything is calculated to excite the most profound emotions. Worldly feelings die away, and piety grows warm when we view its consecrated walls through the obscure and subdued light which streams through the painted windows; when the voice of prayer alone breaks the stillness of its ailes; and, as the sounds of the organ thrill through our souls, we listen to the beautiful and affecting chaunt:—

Stabat mater dolorosa
Juxta crucem lacrymosa
Dum pendebat filius, &c.

During the period of the building of these magnificent structures art was the favourite study of the monks, and the most eminent architects were bred within the walls of the cloister. The abbeys, the cathedrals, and conventual churches, were planned and superintended by successive abbots and bishops; for learning then was a kind of monopoly, and chiefly confined to the clergy, and the nobles of the land. But this was a propitious era for architecture, inasmuch as there was less fear of its being debased by illiterate men. The knowledge of its principles, too, seemed to operate far more powerfully, when concentrated in such a circle, than when scattered in various forms over a whole community. It is thus that the noblest style and the most perfect system of architecture, as seen and universally adopted throughout Europe, is supposed, and with every probability, to have originated among the fraternity of freemasons. For such could only have been accomplished by many different minds acting in concert.

Nor were wealth and labour among the least causes which contributed to this end. To command them is indeed the object of every nation eager of renown, and desirous to distinguish itself by its public institutions and monuments. We admire the beautiful villas of Italy, her lakes and gardens, her palaces and academies for the arts, and we think of the rich cardinals and noble families who built them; we look at other stupendous fabrics and are reminded of the wealth of the Roman patricians. The prelates, too, of the great Catholic churches, from being prohibited to marry, had no motive for accumulating property, but expended it on the service of the altar; and aided by the munificence of princes, the donations of the people, and the revenues arising from monasteries, they were enabled to seek out, from both at home and abroad, the most skilful artists, for the purpose of making those edifices in all respects worthy of religion. Such a capital was applied by the Gothic architects for their embellishment. That unrivalled skill in construction—that elaborate ornament in sculpture, and those beautiful allegorical and legendary decorations, arose from this source. The interior of their churches became one mass of splendour: to compose them, the priests exhausted their knowledge of the passions; and with it they exhausted their fortunes.

The time and labour which were bestowed upon them equally deserve our attention. In our contemplation of any object to which genius has given all the excellence it is capable of, we seldom reflect upon the numerous difficulties through which it has struggled to perfection; although what appears as the effect of enchantment or produced without any effort of the mind, is generally the fruit of many years of painful toil. Those who witnessed the foundation laid of one of these great piles, and those who saw the last stone raised for its completion, were almost two distinct generations. During this long interval, separate portions were built at different times and by different hands; and this was especially the case under the Papacy; so that we find in the history of the cathedrals, a succession of bishops who added some screen, shrine, tower, or transept, in the design of which, they acquired great fame as architects.

This mode of building by degrees is at present rare amongst us. It has been lately followed in one or two parts of England; but the recommendation of it by the "Incorporated Society for promoting the Building of Churches," is likely to lead to its more extensive practice. The only evil that is to be feared will result from it, is the want of unity in design; as we see it in St. Peter's and other works in which this system was pursued.

(To be continued.)

CANDIDUS'S NOTE-BOOK.

FASCICULUS XLVIII.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. It is curious to observe how much fashion and custom prevail in matters where they ought not to be allowed to have any authority. It is still the fashion to talk of Michael Angelo as a "great architect," and he is accordingly considered quite a luminary in that character—a mistake of which some of our now rather numerous Professors would do well to disabuse the public; at any rate those who can admire him and his caprices have no right to turn up their noses at those of Borromini. It is the fashion—with book-making tourists more especially—to extol Palladio, generally in "criticism pilfered from guide-books." And as it is also the fashion to make no mention of Calderari, or any of the buildings designed by him in the same city of Vicenza, the unfortunate Count Ottone is treated as a mere nobody. For tourists of the Trollope breed, who make trading voyages of their travels abroad, and who are content to return home with as much gossiping and blundering as will serve them for a book-making and book-selling job—for such persons there may be an excuse, since, if ignorance can be pleaded as a sufficient one, they may generally claim it most amply; but that a professional man, and one who made architecture the chief object of his journey, should not even so much as once mention Calderari or any work of his either at Vicenza or Verona, is almost incredible—certainly quite unpardonable. Nevertheless, after speaking of Palladio's buildings in the last-mentioned city, Woods says, "I will not trouble you with criticisms on other palaces, where there is nothing particularly beautiful to render them objects of study." Pitiful and humbugging evasion! Did he mean to say that Calderari, a decided *Palladianist* in his style, produced nothing that will bear any comparison with Palladio's own works? If such was really the case, that should have been a reason for his entering into the subject, and explaining wherein the great difference consists, and to what it is owing that, with far fewer solecisms and defects, Calderari's buildings are decidedly inferior to those of Palladio. This might have been rendered a highly interesting and instructive piece of criticism, therefore we may fairly suppose that Woods' reason for passing over Calderari was not that which he has assigned, but the unwillingness to "trouble" *himself* with any farther remarks on the subject of the palazzo architecture of Vicenza. The only mention at all I have ever met with respecting Calderari, in any English book, is—*pace* Joseph Gwilt—in an article on the "Palladian Architecture of Italy," in the *Quarterly Review*, where it pleases the "ignorant reviewer" to remark, "Ottone Calderari particularly distinguished himself by simplicity and elegance, and a knowledge of the true principles on which the beauty of Grecian architecture depends. The Loschi and Bessaro palaces at Vicenza, and the Seminario at Verona, are noble specimens of his skill." Where then were Woods' eyes—where those of the hundreds of others who have visited Vicenza only to prate like so many parrots about Palladio? It is just as if a foreigner, visiting England, should extol Temple Bar as a work of the "great Wren," and of course a perfect architectural gem, yet should not bestow a syllable upon the *palazzi* of Pall Mall. As to Buckingham Palace, the less any one, either foreigner or Englishman, says of that, the better. It is a thousand pities it was ever built, and at least five hundred that it has not since been burnt down.

II. The plea of insanity is now becoming a very fashionable, and is certainly a most convenient one. For some of the things they designed, both Nash and Soane, not to speak of a good many others, deserved to have been hanged; and if tried could have escaped only on the grounds of positive insanity. But then, those who employed them ought to have been hanged too—at any rate, ought to have been shut up in Bethlehem, as being equally insane. Oh! the untold millions squandered away upon lost opportunities! Let us not think of it, for it is enough to drive us all mad, and qualify us for the glorious *privilege* of insanity. Apart from their architectural phrenzies, there was, however, little in common between Nash and Soane; the one lived *en prince* and died a beggar, the other lived very much like a hunks and left a vast fortune, which he most assuredly would not have done could he by any possibility have carried it away with him. I well remember once being witness to a complete *scena*, in which Soane was the actor. In reply to some complimentary remark about his house, he burst out with "D—n the house! curse the house! Could I have my mind, I would tear it all to atoms this very instant—yes, this very instant. I am sick of hearing of it—I abhor it—I detest it—I loath it—I abominate it. And so you are come to see the house?—here is a d—d dull day to come on such an errand. 'Tis as dark as pitch—as black as Erebus. Confound the house, it is my eternal torment, and a parcel of folks are continually coming here, to see the d—d house: they don't come to see *me*—no, I am nobody, they only come to stare at the d—d, infernal, abominable house!" After which furious explosion, and tempest, the old man suddenly became not only tranquil, but very condescending, gracious, and chatty. If he was really mad, there was also a certain degree of method in his madness, and a most extraordinarily queer method it was. "Rich and rare" are the anecdotes that remain to be told of Sir John Soane. I know one who promised to give a collection of them to the public, but he has not kept his word.

III. Independently of the egregious blunders with which it teems, the English translation of Milizia's Lives of celebrated architects, would disgrace a penny-a-liner. That work has been *done* into English, with a vengeance. It seems to have been done by way of exercise while the translator was learning Italian, and in all probability such was really the case. The best part of the book is the index, which as matters go, is saying something in its favour, indexes, even to books of reference, having now gone almost entirely out of fashion. No matter, this is an age when, thanks to the march of intellect, everybody reads and nobody studies.

IV. So Albert has actually shed the light of his countenance and the glory of his presence on the Institute of British Architects; yet his visit to it turned out one of the dullest and flattest affairs imaginable. If the Institute really felt flattered or encouraged by it, they must be the most easily satisfied mortals breathing. Of course all was conducted very "properly;" no blunders were committed either on the one side or the other. The Prince was exceedingly prudent and discreet—which for a Prince, is saying something: he did not attempt any compliments; he did not pretend to congratulate the Institute on their unwearied zeal, and on what they had done for the advancement of architecture in this country. In abstaining altogether from *blarney*, his Royal Highness showed good taste, but he certainly did not manifest the slightest cordiality or sympathy with them. The whole affair was mere matter of form and ceremony—at once perfectly correct and intolerably chilling. The Prince seemed to consider it a bore—how the others relished the taste they got of Royal condescension and patronage, I pretend not to say. There was, at all events, a paragraph for them in the newspapers and *Court Circular;* but as to the patronage itself, that is likely to turn out a mere phantom—of just as much real service to the Institute, as the Institute itself is to the art and the profession.

V. "I cannot recommend frescos," says Mr. Eastlake, "for the sitting rooms of dwelling houses;" a very reasonable piece of advice, now that we seem to be threatened with a fresco mania. If that mode of painting is to be employed for the merely general decoration of walls, it would soon sink to the level of paper-hanging, and its greater pretension would chiefly serve to render it all the more paltry and unsatisfactory. On the other hand, if it is to be employed for subjects upon a large scale, and with figures of the size of life, it would be a most obtrusive and oppressive species of decoration. In that respect painted ceilings are objectionable enough, but they are comparatively quite removed from notice. Saints and virtues may cut capers over our heads, and dance jigs in the clouds, without our being compelled to look at them; but it would be very different were the walls of our rooms to be peopled with such figures—poetical or historical, and converted into so many "scenes." Pictures in frames do not force themselves importunately upon our attention: while they contribute to general embellishment, they do not *insist* upon being looked at; but we may do so or not according to the humour of the moment. Few would relish dwelling in rooms where the same scene, be it either solemn or the contrary, is constantly acted before their eyes. However masterly the paintings themselves might be, they would soon sicken of being shut up in a Miltonic "Paradise" or "Pandemonium," or a Dantean "Inferno:" while a perpetual Elysium would be likely to inspire them with the blue devils. Nay it is not every picture that one would care to have hung up in a drawing-room or other domestic apartment: the "Lazarus" of the National Gallery, for instance, would not be particularly desirable or exhilirating as a companion in such a place. It is all very well to talk about fresco-painting and the grand style of art; yet it does not follow that we are bound to admit them into our houses. They neither suit us, nor do we suit them; which may be unlucky, but is nevertheless the case. The truth is, we are a very matter-of-fact people, and live in a very matter-of-fact age; nor will all the arguing in the world render us otherwise, for we might as well attempt to change the natural atmosphere, as the moral one which surrounds us. It is very easy to say, let us revive this, or revive that: but how are we to infuse actual life and vitality into that which has been extinct long ago? The utmost we can do is to conjure up the mere ghost of it, and for ghosts the world has now little relish. The king of Prussia is now endeavouring to revive the Greek theatre and Greek drama in their pristine purity; and he will do so—but how?—precisely after the manner in which Eglintoun brought back again the age of chivalry, with its pageants and tournaments. It would perhaps be wrong to say that art in this country is not yet *ripe* enough for fresco painting, since it is more likely to be too *rotten*.

SUGGESTIONS FOR THE MORE EXTENSIVE EMPLOYMENT OF CONCRETE IN DISTRICTS WHICH DO NOT POSSESS ROCKS SUITABLE FOR BUILDING PURPOSES.

It is now many years since our active neighbours, the French, undertook on a very large scale, the manufacture of artificial hydraulic limes, with a view principally to introduce them as an ingredient into that species of concrete which they have termed béton. Following in the track of Berthier, Vicat, and Treussart, our own countryman, General Pasley, has long since endeavoured to arouse the attention of landed proprietors, engineers, architects, builders and others, to the method of forming artificial cement, by the mixture of chalk and clay in certain proportions, which should vary according to the qualities of these two ingredients. Hitherto, however, notwithstanding the perfect success which has attended the manufacture in the neighbourhood of Paris, where it is carried on at this day on the very same principles as those which General Pasley first had the credit of introducing to this country, nothing has yet been done by ourselves to carry out the practical application of a process which is evidently calculated to afford a very fine field for the employment of labour, the exercise of skill and ingenuity, and the profitable investment of capital.

Under the general head of calcareous concretes may be classed all those substances which are composed of fluid mortar mixed with broken stones, gravel, pebbles, fragments of bricks and tiles, or such other hard mineral substance as may be at hand. An ordinary concrete is that which is made from a common chalk or other lime stone which does not possess the property of setting under water. On the other hand, the quick setting limes, and those which possess hydraulic properties, as the Barrow lime, the Aberthan, that of Lyme Regis, and other places, as the lias formation, compose the species of concrete which is termed béton. Now it is known that all the limes which have been mentioned, owe their hydraulic property principally to the presence of a small quantity of clay in intimate combination with the lime. Hence it is that Roman cement, which is burnt from an argillaceous limestone containing more clay than any of the beforementioned, and indeed more than any of the rocks properly called limestones, forms in concrete a more perfect kind of béton than any other. Conceiving an ordinary limestone to form a simple concrete, and conceiving Roman cement to form a true béton, all other kinds of limestone may be considered capable of forming a mixture intermediate between simple concrete and true béton, according to the proportion of argillaceous matter they contain.

It is quite a mistake to suppose that the béton so much in use throughout France, Holland, Italy, and other states on the continent, is invariably composed of broken stones mixed with lime, &c. Such appears to be a mistake into which O. T. of Newcastle has fallen in his paper on concrete, in the *Journal* of February last, since he observes "that béton differs from concrete in broken stone being used instead of gravel, in the proportion of two of stone to one of lime or pozzolana of Italy, &c." Now the truth is, that although broken or angular stones are commonly used in the manufacture of béton, yet gravel and pebbles are not unfrequently made use of; and the real and true distinction between concrete and béton lies, as we have already said, in the employment for the latter of a more or less hydraulic lime instead of a lime made use of for ordinary mortar.

Among the best of the hydraulic limes employed for the French béton, may be mentioned that of Metz and that of Senonche near Dreux. The hydraulic limes of Tournay in Flanders and of Viviers upon the Rhine, are also of excellent quality. The hydraulic limes manufactured in the neighbourhood of Paris are composed of three parts of chalk ground into powder, and made up into paste with two parts of plastic clay. This mixture is formed into cakes, burnt in a kiln, and then ground to powder.

Application of Concrete to building purposes.

The Romans extensively employed concrete not only in building walls of every description, but even constructed vaults and arches entirely of this substance. Examples of this are found in the remains of their baths, their theatres and temples. The arches in the Coliseum, in the baths of Caracalla, in the temples of Peace, of Minerva, and of Venus, are mostly of concrete with an occasional rib of brickwork.

The spherical vault of the Pantheon at Rome, which is 133 Roman feet in diameter, and also a great vault at the baths of Dioclesian 71 feet in diameter, were both built of concrete, and their condition is as perfect at this day in point of stability as when they were first erected. A more modern example exists in the great concrete vault for the dome of St. Peter's, which is 82 Roman feet in diameter, and 141 in height. While admitting that the excellent preservation of many Roman walls in Italy, Spain, and the south of France, clearly proves the almost imperishable nature of the concrete or béton of which they are composed, it has been objected by many modern architects, that the variable climate of Great Britain is unfavourable to the duration of concrete in exposed situations, and the opponents of concrete have not hesitated to affirm that, if those Roman monuments, whose preservation we so much admire, had been tested beneath a more changeable sky, and exposed to the rigors of a more northern clime, they would have furnished far different evidence, that is, far less favourable evidence of the value of concrete for building purposes. In reply to this, however, it will be sufficient to adduce numerous old castles which were built in this country soon after the Norman conquest, and whose walls, consisting of irregular masonry, which bears a close resemblance to béton, are found at this day in a state of excellent preservation. The great Pictish wall, which is well known to have been executed by the Romans, is also a striking instance of the durability of well composed béton; and upon the whole we are justified in concluding from ancient remains existing in our own country, that where good hydraulic lime is employed, béton will last even in the atmosphere of Great Britain, for at least as many centuries as most of the stones at present employed for building purposes. We have observed in the walls of many old castles in England, that the stones have been greatly decomposed and eaten away by atmospheric influence, while the mortar joints stand out in relief and indicate what was originally the face of the work. In such cases the mortar has been obviously far superior to the stone, and this superiority is further evident, by trying the relative hardness of the two. While the stone will crumble away and yield to any metallic edge applied to it, the mortar can only be impressed with considerable effort. Now we do not hesitate to affirm that the same excellence as that for which the ancient mortar is so celebrated, has never ceased to be within our reach in this country, which is fortunately favoured by an abundance of the materials most proper for the purpose. In works of this kind the ancients had no secret with which we are unacquainted, but on the other hand, the researches of modern chemistry have brought to light a great deal connected with the subject of mortars and cements which in all probability our ancestors knew nothing about. The fabrication of artificial cements and hydraulic limes is entirely a modern discovery, and one of which the Romans were perfectly ignorant.

It appears quite clear, from all we can gather on the subject, that the superiority of ancient mortar depended chiefly on a judicious choice of good stone for the purpose of burning into lime, and afterwards upon careful attention to the manipulation of the calcined lime; and such being the case, there is no reason on earth why modern buildings of every kind should be constructed of materials less imperishable than those which our Roman and Norman ancestors made use of.

The great sea wall at Brighton, the dock walls constructed of concrete at Woolwich, and a church said to have been lately built near Brighton entirely of concrete, afford examples of what may be effected by this material. It is quite certain, however, that several circumstances have most unfavourably operated to retard the more general employment of this most valuable substance. Among the foremost of these, we cannot avoid referring to the patent which was taken out a few years since for forming concrete into artificial stones. The signal failure which attended the use of this artificial stone in some government buildings at Woolwich and other places, has too hastily led many engineers and architects to regard as impracticable the employment of concrete or béton for building above the surface of the ground. But let us observe the difference between small blocks of stone formed of concrete and the firm cohesive body which the substance presents when used *en masse*, as it always should be. The stones which were manufactured of concrete were found, as might have been expected, so tender and brittle at every corner and arris, that it was almost impossible to preserve them with perfect edges up to the time when they were set in the work. The process of setting them by mortar in the same way as ordinary stones, left these tender arises still exposed to injury, and it was no wonder that all along the joints a destruction of the walls took place to a very serious extent. It appears to have been the practice, in forming these artificial stones, to face them with a kind of plastering, which is said to have pealed off in great quantities from the action of frost and other external influences. We repeat that this absurd project for making concrete into blocks of stone has greatly impeded the real advantages of concrete from being properly appreciated. We protest, however, most strongly against any inference being drawn unfavourable to a judicious use of concrete from the failure of this attempt to form it into artificial stone.

According to the system of building with concrete, which we propose, the walls should in all cases have coins and coping of stone or brick, so that only a smooth plain face of concrete will be exposed. By adopting this method, no sharp corners or edges will be liable to injury from external violence, and there will be no irregularity or broken roughness in the work to admit the lodgment of moisture and occasion that injury which always takes place when frost ensues. To substitute a pile of separate cubical blocks of concrete for the solid mass of which a building may be at once constructed, appears to us in no respect more rational than the act of a man, who in proceeding to found upon solid rock, should break the rock in pieces, and join these pieces separately together, instead of founding at once upon the solid material. It may be said that we employ stone and bricks in cubical blocks of small dimensions, but this is a matter of necessity not of choice. Nature furnishes in the quarry blocks of stone, which have a fixed and limited size according to the natural beds, joints and fissures by which the strata have been divided, and in the case of bricks the convenience of manufacture, particularly with reference to the condition of being properly burnt, limits the size to comparatively very small dimensions. In building with concrete, however, no such limits exist, and there can be no comparison between the expediency of fabricating little detached pieces of concrete stone, and that of raising the whole mass of any house, wall, or building, by united and continuous layers extending without a joint over the whole area of the building.

In seeking for another cause why concrete or béton has not been successfully employed of late years in this country for building above the surface of the ground, we are strongly inclined to the belief that a fair and workmanlike attempt has never been made under judicious superintendence to apply a good hydraulic lime to this purpose. It is indispensable, in constructions of this kind, that the lime should possess some degree of hydraulicity, in order that it may harden before the injurious action of frost comes upon it. It is generally admitted, that mortar which contains no hydraulic principle, that is, mortar made from pure, or as they are technically called, fat limes, require a very long time to set perfectly hard; and it has even been asserted by experimentalists, who are well worthy of credit, that mortar has been found in a soft pasty state several years after it had been used in a building. On the other hand, hydraulic lime will harden in a very short time—requiring, in fact, a period which varies inversely with the strength of its hydraulic principle, this period, in the case of Roman cement, the most hydraulic of all mortars, seldom exceeding a few hours. The readiness with which concrete, composed of strong hydraulic lime, is found to set, confers peculiar value on béton for building purposes, because when once hardened, it is no longer subject to be affected by atmospheric changes, and may safely defy the influence of rain, moisture, frost, and the other destructive means by which imperfectly hardened mortar is so speedily destroyed.

As we have no wish to disguise or conceal what may be called the unfavourable side of this question, it may be as well to refer in this place to the opinions expressed by Lieutenant Denison and other officers of engineers, upon the use of concrete for building purposes. The opinions of these gentlemen are hostile to the employment of concrete, and are founded upon experiments and observations made upon concrete walls at Woolwich and some other places. Now we are perfectly ready to give every possible credit to the officers of engineers, for the care with which these experiments were made, and the fidelity with which these results have been recorded. We believe them also to have been free from any prejudice against concrete in the first instance; but granting all this, we are greatly mistaken if they have made use of the right material. Their experiments appear to have been made upon a simple concrete instead of a true béton, and owing to the long time which the former requires to harden in this climate, it was found to have been dissolved by water, and to have been shattered by frost before it had been allowed time to set. When we look at the undoubted fact, that constructions of béton have actually been practised in France with great success, within the last few years, there are only two ways of reconciling the anomaly which their reputed failure in this country appears to exhibit. Either the experiments have not been made with proper care and with good faith, or they have been made upon the wrong substance. At once, without a moment's hesitation, we reject the former supposition, and decide that the latter must have been the case.

In order that no doubt may remain on the minds of the sceptical with respect to the perfect success which has attended the use of béton for actual building in France, and at the same time to convey some knowledge of the process and style of building adopted, we shall here lay before our readers some particulars of a dwelling house lately constructed entirely of béton, by M. Jean Auguste Lebrun, upon his estate at Marsac near Albi, in the department of Tarn. This building consists of three stories, with three rooms in each floor, and a large granary or garret at the top. Along the front of the house extends a gallery which has a height equal to that of the building itself. Not only are the walls of this house composed of béton, but each floor is supported upon arches of béton thrown across from one wall to the other, so that throughout the whole building scarcely a particle of timber is made use of. The arches which support the first or principal floor have the following dimensions.

That for the gallery or passage, has a chord or span of 10 ft., a rise of 1 ft. and a thickness at the crown of 4½ in. The three arches which support the three rooms of this floor are each 17 ft. 4 in. in span, with a rise of 3 ft. 3 in., and a thickness of 10 in. at the crown. The roof of the building is formed by two semicircular arches, one covering the granary already mentioned and the other covering the gallery. The principal of these arches has a span of 20 ft. 3 in., with a thickness of 10 in. at the springing and 6 in. at the crown. The smaller arch over the gallery is 10 ft. in diameter, with a thickness of 6 in. at the springing, and of only 3 in. at the crown.

The béton was generally composed in the following proportions—

One part of lime slacked by immersion;

One part and a half of pure sand:

And two parts of gravel or broken flints, from 3 to 5 in. in diameter, according to the thickness of the walls in which they were to be employed. Thus the largest stones were used for the thick exterior walls, those of smaller size for the large arches, and the smallest of all for minute arches and ornamental mouldings on the outside.

The béton was in the first place well mixed up by hand labour, and then thrown into a framework or encaissement in regular courses of 1 ft. in thickness. This encaisement was simply composed of a few uprights, to which were secured horizontal planks placed on edge one above the other at the proper distance apart, so that when removed, the béton filled in between them shall occupy the proper thickness required for the wall. This method of raising the walls in courses of about 12 in. deep, appears to have been practised by the ancients in building with béton. The system will be quite familiar to those of our readers who have even witnessed the building of mud or earthen walls, as practised at this day in the Lyonnois and other parts of France, in the eastern countries, and in a ruder form even in this country and in Ireland. The arches for supporting the floors were turned upon centres of the usual kind, and the exterior mouldings in front of the house consist of béton filled into moulds prepared to receive it. A thin layer of lime mortar was plastered over the exposed surfaces of the walls. This plastering was pointed to a sharp arris at all the exposed edges, and seemed to give to the whole structure an appearance of smoothness and regularity which could not be expected from the naked béton.

In the summer time the béton of one course was generally sufficiently set in six hours to admit of the next course being filled in, and about twelve hours were required in spring time. As each course was regularly completed throughout over the whole area of the walls, the part which had been first filled in was commonly set by the time the course was finished, so that no delay took place on the completion of the separate courses. The centres for the arches of the gallery were struck at the end of a month after its completion, and those of the large arches were removed at the end of two months and a half. It was found that after this interval the béton had acquired so much consistency as to produce no thrust upon the abutments.

The exterior surface of the front wall, and the outside of the great arch which forms the roof, were painted with several coats of oil paint. This was done as much for the purposes of decoration as to enable the surface to withstand more perfectly the rain and frosts of the succeeding winter. It was found afterwards, however, as far as durability was concerned, this precaution was unnecessary, for those parts which had not been covered with paint, perfectly resisted all the rigors of the most severe seasons.

Not only has M. Lebruce, the architect who constructed this building, declared its perfect condition, after the lapse of two years, but he has accompanied a report, which he addressed to the *Société d'Encourag-ment*, with certificates from the prefect of the department of Tarn and the sub-prefect of the arrondissement of Gaillac, both of which attest the perfect solidity of the building, and state that it presents all the appearance of stone. In order to try the strength of one of the arches supporting the principal floor, it was loaded three months after the centres were struck, with a mass of earth 10 feet in thickness, and extending over the whole top surface of the arch. The weight thus applied amounted to 1250 lb. per square foot, or about eight times as much as that which a floor supports when a room is full of people, and this weight was borne without the slightest injury to the arch.

The great economy of this method of building is highly important. It appears that the cost of the whole work was no more than 5*s*. 3*d*. per cubic yard, which is about one-third the price of brickwork in that part of France.

It may be necessary to explain that the process of slacking lime by immersion, which is mentioned in a former part of this description, is performed in the following manner. The lime stone, after being burnt, is taken from the kiln and placed in a pan in pieces from the size of a walnut to that of an egg. The pan is then plunged for a few seconds into water, and withdrawn as soon as the lime begins to emit heat. After this operation, the lime continues to heat and swell and falls at length into powder. It is placed in this state in chests or casks, where the heat being concentrated, and a great part of the moisture being condensed and not allowed to escape in steam, will be again taken in by the lime which is then more perfectly slacked than otherwise. If the lime is intended to be kept any time before being used, the chests or casks should be covered with straw and placed in a perfectly dry place entirely removed from any danger of being penetrated by any kind of moisture.

(To be continued.)

ARE SYNCHRONISM AND UNIFORMITY OF STYLE ESSENTIAL TO BEAUTY AND PROPRIETY IN ARCHITECTURE?

An Essay to which was not awarded the medal of the Institute.

By a Student.

The question whether synchronism and uniformity of style are essential to beauty and propriety in architecture, is so novel, that it might have been well had the Institute of British Architects accompanied their proposition by some definition of the terms in which it is conveyed—or at least set some limit to the sense in which they are to be understood.

Of all the arts and sciences, none has ever been, or must necessarily be, more strongly affected by the inexorable course of circumstances, than architecture. None has been found more essential to the civilized existence of mankind. None has contributed more to the comforts of the humble, to the grandeur of the mighty, or to the gratification of the refined perceptions of those blessed with taste. None has so perfectly attained the combination of the useful and the beautiful. Since architecture assumed the conditions of an art, human genius has been on the stretch in every period and in every community, to bend its capabilities to existing manners and circumstances, and to study the modifications dictated by climate, by religion, by the comparative progress of the sister arts, by the state of mechanical science, and the minor effects exercised by soil and the choice of materials.

That architecture, practised during a long succession of ages, and modified by these and many other influences, moral and physical, should have exhibited the most opposite extremes in style, seems a necessary condition of its existence as an art. If, therefore, by synchronism and uniformity is to be understood the strict adherence, at the present period and in the locality of Great Britain, to any style of architecture appropriate to any other period or any other locality, such a condition seems *primâ facie* not only *not* essential to beauty and propriety, but to be utterly incompatible with any state of architecture worthy to be dignified by the name of art. It may be asserted that no such principle has ever obtained in any recognized school of architecture, and its conception seems altogether due to the new light, (or darkness visible,) thrown upon architecture some fifty or sixty years since.

Widely as the styles of architecture, which the lapse of ages has spread over Europe, may differ from each other—numerous as may be the subordinate varieties to which the great divisions of style may have given rise—the elements of all will be found few and simple. The origin of the existing architecture of Europe, must be sought in the works of the Greeks. The inventive faculties, and the fine perceptions of that people, have produced the most perfect adaptation of the means afforded by architecture to the end upon which they were employed, that has ever existed, and more perfect than can ever exist again; because the objects to which their architecture was adapted were compatible with its simplest forms. Until other nations have the same objects to fulfil, they never can use the same simple means with equal propriety, nor consequently produce by them the union of usefulness and beauty in the same degree. The simplicity of Greek architecture, its *oneness*, (to use a phrase of the cockney poets,) is the element which not only forbids its reproduction synchronically, but defies the invention of its parallel. To the simple elements which the felicitous genius of the Greeks reduced to the conditions of an art, may be traced all the systems of architecture which have followed in succession. From the Greek to the Roman, from the Roman to the Romanesque, from thence to the Byzantine in one direction, and to the Arabesque in another, from the Byzantine to the later Romanesque, and from thence to the Gothic, from the Gothic again to the Italian Renaissance, and from thence to the classical Italian schools, and the French and English schools of the 17th century, are transitions familiar to every architect who has studied the history of his art. These are styles, every one of which, judged by the circumstances under which it arose, and the purposes to which it was applied, whether civil, military, or ecclesiastical, will bear the severest test by which architecture can be tried—the test of usefulness, propriety, and beauty, mutually dependant upon each other. But where among them is to be found what it is presumed the Institute mean by synchronism and uniformity of style? If the hypothesis be founded that Greek architecture owes its origin to the Egyptians, it is evident that it never could have existed at all had the Greeks been infected with such a principle.

After ages of prosperity, English architecture languished in the hands of the followers of Lord Burlington. To something analogous to this synchronism we may perhaps trace its decay, since the unmitigated imitations of Palladio by the Burlington school, ended by driving the public taste to take refuge from their insipidity in the frippery decorations of the Adams.

The publication of the discoveries of Athenian Stuart was hailed as the means of a thorough regeneration of architecture. Greek and Roman republicanism shortly after filled the mouths of the orators of Europe, and the simplicity of the Greek style carried with it a prejudice that it might be "*done cheap*." Under these circumstances Greek architecture appealed forcibly to the vulgar. Those who really felt and appreciated its exquisite purity and refinement, unfortunately overlooked the fact, that those very qualities rendered it inflexible to the combinations necessary to adapt classical architecture to modern requisitions. The Romans knew better. When they adopted the orders of the Greeks, they modified them with consummate skill, to fit them for combination with the arch and with each other. The modern Greek school jumped to a different conclusion, as logical as the sentence which annihilated the Alexandrian library. Greek architecture, like the Koran, being perfection, nothing could be necessary or expedient which was not contained therein, and in this conclusion triumphed the principle of synchronism. A brilliant popularity could scarcely fail to attend a doctrine pointing out a royal road to architecture, rendering superfluous the tedious study of the theory, the philosophy, nay, the very grammar of the art, and conducting to the glory of a Callicrates or an Apollodorus, every possessor of a Stuart's Athens and a pair of compasses. Roman architecture was rejected as spurious—the Italian schools dismissed with contempt—Inigo Jones esteemed an ignoramus—Wren a bungler—Vanbrugh a barbarian—Burlington a humbug—Chambers an imbecile. They built no Greek! As reasonably may Burke or Canning be decried for not declaiming in Greek. The principle would place Chatham below the school-boy who spouts a Greek oration by rote—no inapt parallel to the architect who compounds his odds and ends out of Stuart's Athens (not forgetting the supplements to eke out his ready made portico, and looks with disdain upon Vignola and Perrault. If we suppose the boy's oration to consist of unconnected words like nonsense verses, the similitude may run a little closer.

Had Greek architecture been studied in a Greek spirit, important advantages might have resulted from its revival, but it is by no means certain that its peculiar forms and character will ever permit it to be amalgamated into any such combinations as the Italians have effected with the Roman, the flexibility of which, as displayed in their hands, enabled it to become the universal style of modern Europe, (modified by each country according to its wants,) until the Greek mania superseded it in Great Britain. *Purity* has ever been the ultimatum insisted upon by the advocates of the Greek style; but if a Greek architect could rise from the dead he would scarcely admit the purity of Anglo-Greek architecture. To face a building with an *avant-corps* much below its height, for the sake of introducing a single order—to back a Greek Doric portico with two stories of windows, or to flank it with arches cut into segments, and shorn of their impost and archivolt, that if they are not Greek they may at least look like nothing else—to associate the most decorative modification of the Greek Ionic, with doors and windows mulcted of their architraves—to condemn pilasters as a Roman invention, and to range Greek antæ on a wall—to force into combination two or three crude imitations of Athenian buildings where one has been found unmanageable—our resuscitated Greek would surely not admit that either the letter or the spirit of his art had been followed in such treatment of it.

These observations on Greek architecture, in its modern acceptation, have been put forward, because it is to the introduction of this style that the principle now recognized by the Institute under the name of synchronism is chiefly due, and its failure most signally apparent—so much so, that the argument may be thought levelled at a by-gone subject of discussion. The error is not, however, so worn out, but that designs may still be seen for purifying St. Paul's, by elevating a couple of lanterns of Demosthenes at the west end—opinions still heard, that Blenheim might be improved by the infusion of a little Athenian detail—commiseration still bestowed on Sir Christopher Wren, for the limited intelligence upon architecture in his time. If these freaks of fancy be not so rife as they may have been at an earlier period of the present century, they have been replaced by others not more to the credit of British architecture, upon which there will be a few words to say presently. In the mean time, it may be observed, that if synchronism and uniformity of style be indeed essential to propriety and beauty, then have the architects of the world been in a long error of some three and twenty centuries. Admit the principle of synchronism, and architecture ought to have stood still since it attained perfection at Athens. The Coliseum, the Thermæ, the Basilicas, Santa Sophia, the Alhambra, the churches of Amiens and Salisbury, the Vatican, the Palazzo Farnese, the Louvre, and a few other works by a few other architects, to which and to whom the world in general, down to the ultra-enlightened period of modern Greek, have agreed to allow some meed of praise, must all be denounced as worthless, should synchronism be essential to beauty and propriety, since they have all arisen from the perpetual state of transition of the art. What aberration from synchronism and uniformity is to be tolerated for the purpose of forming new styles? Where is the line to be drawn by which different styles ought to have been set apart as worthy to afford a new starting point for synchronous treatment, or where are they to be separated for the future? Or are the architects of the present day alone to be limited to the servile imitation of styles gone before, and their whole intelligence limited to treating them synchronously, excluding invention and the study of character and fitness as beyond their comprehension? What style is to be selected as best fitted to our exigencies—or are we to set up here a bit of Greek, there a bit of Italian, Arabesque in this place, Cinquecento in that, Gothic or Egyptian in another, to show how perfectly we have studied synchronism and nothing else! Forbid it ye sacred muses! and forbid the Institute of British Architects to entertain questions which expose them to the eyes of all Europe as plagiarists and imitators *prepensé!*

Of late years, our ancient national architecture has occupied much of our study, and the investigation of its transitions has done much to fix this said principle of synchronism upon our practice. It is a wretchedly narrow path which our architects have chosen, and it is to be hoped that it may widen as it is pursued. It has certainly expanded since a Gothic cloister of the 13th century was erected for a ball-room (at Belvoir castle.) This work is executed with a knowledge of style and detail, with an attention to synchronism in one word, which leaves nothing to be desired so far: and it is evident that the clerical amateur architect, who has to answer for this performance, was perfectly innocent of the knowledge that anything was to be desired beyond it. Let us hope that such an error may not infect our professional practice, and that we may not be too complaisant in yielding to the prejudices and prepossessions, which a march of ignorance, unparalleled in activity and impudence, is just now spreading through the land in the shape of "a little learning." Our Gothic architecture and the peculiar national modification of the Italian which succeeded it, have been extinguished upwards of two centuries. The reformation of the church in the first place, and the alteration in our habits and customs since the erection of the last of those domestic edifices which it is now the fashion to revive, point to the necessity of some modification of the architecture of the middle ages, both ecclesiastical and civil, not very consistent with the principle of synchronism and uniformity. This consideration leads to a question involving these principles in something like a dilemma.

How are we to dispose of the mixed style which forms the principal stock in trade of this revival as far as domestic architecture is concerned?

The remains of the habitable portions of our great castles, and of some few buildings of a more purely domestic character, show clearly that in the earlier period of our architectural history, little attention was paid to the internal fittings, which now constitute the necessary comfort of our mansions, even of the most moderate class. Bare walls and such inconveniences as attend grated windows and ill-closed doors, were the general lot of those who could not afford the luxury of tapestry. Wainscot linings were not unknown, but their use was certainly not common, and none of an early date have survived. By the time a demand for more habitable interiors became general, the Gothic style was on the wane, and we may be troubled to find an interior among our ancient mansions, fitted up in a manner approaching even the commonest exigences of the present day, in which the wood and plaster work does not bear another character, although the fabric itself may be very unexceptionable Gothic. How far this mixture was carried, and how far it presently affected the fabric, it is unnecessary here to explain—but it may be observed, that the first Italian architect whose works are still extant in England, exercised his discretion in some very important modifications of the style he imported. The works of John of Padua exhibit as genuine a specimen of the school of architecture to which he belonged, as will be found in Lombardy itself—but with this difference—he adopted the English window and the English chimney. It did not enter into the mind of this distinguished architect, to condemn his clients to darkness and damp, for the sake of following the arrangements expedient in his own climate—in other words, he did not think synchronism and uniformity of style necessary to beauty and propriety. The example set by John of Padua became the type of the architecture of Elizabeth and James I, and the question is, when we recognize this mixture as a distinct style, and follow it, as the fashion now is, do we not set synchronism and uniformity in direct opposition to each other?

Some modern examples there are, of interior fittings founded altogether upon Gothic forms, but certainly possessing nothing of the Gothic character. A plaster cornice bordering a flat plaster ceiling is not Gothic, however scrupulously the mouldings may be profiled or the foliage modelled—a sash window with its apparatus of folding shutters is not Gothic, however artfully its structure may be disguised —a door case with its architrave and cornice, rebated jamb linings and butt hinges, is not Gothic, though its head may be pointed, and most orthodox putty squeezes glued into the spandrils—and yet this sort of internal architecture has been coined, in preference to adopting what was considered an inconsistency, though practised boldly and successfully by our ancestors of the 16th century.

Perhaps we are held bound, when circumstances call upon us to work out an early style of Gothic, to make everything cold and comfortless for the sake of synchronism and uniformity. This position would undoubtedly solve the dilemma, and the architect would then only have to persuade the inhabitants of his dungeon to dress themselves in the ancient costume and cultivate their beards, to speak Norman French, pray in Latin, eat with their fingers, and drink ale out of leather black jacks for breakfast, in order to earn immortal glory as a restorer of the arts.

We may aptly conclude with the following observations of the late Allan Cunningham—

"We never can lawfully become heirs to the fame of men who wrought in other lands and died three thousand years ago. No poet will claim as much merit from translating Homer or Dante, though he should excel Cowper or Cary, as he would deem his due had he written a Fairy Queen or a Task—but your architectural copyist takes a much loftier view of himself—he imagines he has achieved something truly grand, when he has persuaded a prince or a peer to have a house, every pillar and architrave of which can be justified from antique example. This servile spirit disgraces the architecture of our country—Greece will never surrender to us the honour of her porticos, or Italy of her elevations, and there is the more reason that we should dwell on the memories of such men as Wykeham and Vanburgh, whose genius, whatever else we may say of it, has at least given us architecture that we can honestly call our own."

THE CHAPTER HOUSE OF SALISBURY CATHEDRAL.

Read before the Institute of British Architects.

By T. H. Wyatt, Esq., Fellow.

Mr. Chairman & Gentlemen—I have always felt that there are no subjects of communication which may be made more generally useful to our members, than observations on *points of questionable construction*, or *propriety of style and date*, occurring, as they frequently must, in our practice. The paper read at our last meeting by Mr. Granville, has strongly confirmed me in this belief; it was one which could not fail to interest and instruct all who heard it. Acting, then, on this strong conviction, I venture to lay before you the particulars of a case which will, I believe, well repay its consideration.

The Chapter House of Salisbury Cathedral having fallen into a neglected if not a dilapidated condition, and the Lord Bishop of that diocese, being desirous to take upon himself the restoration of this interesting building (and so far to assist the funds at the disposal of the chapter, already hardly sufficient for the mere repair of the Cathedral itself), did my partner and myself the honour to ask for a report as to its present condition, and advice as to its entire restoration.

My first step was to inform myself of the history of this portion of the Cathedral group, and I referred to a variety of works bearing on the subject, and to such records as existed in the Cathedral library, at all likely to assist in the inquiry; but the amount of information they furnish is very slight, the Cathedral itself usurping, in all of them, almost exclusive consideration. There is no record of the exact period when this room (if I may call it so) was built, or in whose bishoprick. It is supposed to have been commenced a few years after the completion of the Cathedral in 1258, and its design is attributed to Bishop Bridport, who died in 1262. Price, in his history, published in 1753, merely affirms, "that by several diligent searches into and careful inspections upon the nature of the work, I find that the Cloisters, Chapter House, and Monument Room, were not begun till the Cathedral was considerably advanced, because the stone-work is not bonded together, as it must have been had all been carried on together, though manifestly by the same architect." But by whomsoever built, it must have been, in its original state, "with its central clustered columns, its vaulted roof and ramified ribs, its light, large and lofty windows, all decorated with stained glass, its sculpture, and a floor paved with richly glazed tiles," perhaps the most beautiful room of its class in Europe; or as Gilpin says, "nothing in architecture being more pleasing." The only paper or notice relating to it which I can hear of amongst the Cathedral records, is the following quaint report made in 1691, by a Mr. Thomas Naish, clerk of the works to the fabric; with an estimate of the charge of bringing it into good repair. "And first to begin with what threatens the suddenest ruin! The Chapter House is an octagon of 68 feet diameter built with too slight abutments to support the thrust of the vaulting, the least space of time (the weight of the former being too little for the throst of the latter) were not the springers of the vaulting braced together with 8 bars of iron united at the centre, and fixed in hooks at each angle, which hooks are gutted with lead to fix them to the wall; but by the thrust of the arching several of these hooks are drawn out of their first place, some six inches, some more, some less; by which means the vault is spread and hath rent the walls in several places 3 in. or 4 in. wide, and drawn the columns which standeth in the middle (being not more than 16 in. diameter) about 6 in. from its perpendicular, and by a small declension further, must in all likelihood fall to the ground. The roof is also decayed, *and thrusts the walls outwards and helps towards its ruin.* Some of the buttresses are decayed at foot, the stones being loose or scaled by frost. Part of the walls between the vaulting and roof is by some former wet (*qy.* rent?) so shattered that it scarce well supports the roof. The mullions of windows also are scaled by the rusting of the iron bars that are fixed in them, and some of the tracery work like to drop by the spreading of the walls.

"The core proposed is, a brace of iron round each buttress, fixed to the bars which now are in the crooks, which need be 3 in. broad and 1 in. thick, and will weigh the whole eight, 2160 lb. at 6*d.* per lb. amounts to 54*l.*

"An iron band quite round the Chapter House on the top of the windows, of the same dimensions, will weigh 2500 lb. at 6*d.* per lb. = 62*l.* 10*s.*

"Repairing the defective part of the timber work of roof, 40*l.*

"Repairing the walls between the vaulting and roof, new footing the butments where decayed! Restoring the mullions that are scaled and broken, and new pointing and keying of the walls and vaulting where rent, and all mason's work, 90*l.* Total 246*l.* 10."

So much for the only official document existing! The only portions of restoration which I can give Mr. Naish credit for having carried out, are as follows:

1st. Rendering the iron ties more effective than they could have been when merely gutted in (although not done as he proposed).

2nd. Certain repairs to the feet of buttresses. Of all his other grounds of lamentation, I see no proof that they were attended to. The iron band round the head of the windows was never introduced. The defective parts of roof, of walling between the roof and the vaulting, and the tracery of the windows may have been repaired, but certainly not in a manner to do credit to Mr. Naish's constructive powers. I am at a loss to reconcile his assertion, "that without the eight iron ties, the vault could not stand *the least space of time*," with the current report that Sir Christopher Wren introduced these ties; seeing that the building must have been completed 400 years before Sir Christopher reported in 1669. How far it is probable that the author or authors of this beautiful design would have introduced so clumsy a means of support, (even if they had subsequently imagined their abutment weak) when they had under their eyes the "magic flying buttress" so lavishly used in the Cathedral, I leave the admirers of Gothic architecture to determine. In Sir Christopher Wren's report on the Cathedral and spire, there is not a word as to the Chapter House; an omission not very probable if he had felt it necessary to have recourse to such a remedy. They were probably introduced at a period previous to his, and consequently to Mr. Naish's report, when either the present injurious roof (or the high pitched one which I doubt not originally existed) may have exercised a far more dangerous effect in the central column than any thrust from the groin. I will now proceed to describe the state in which I have found this building.

The present roof is a flat one, rising to the level of the parapet, as at Wells and as at Lincoln (previous to 1800, when the high pitched roof was restored). It is covered with heavy lead, by no means in a weather-tight condition. The construction of the roof is of the most primitive order, and has exercised a very injurious effect on the walls and on the centre pillar. Its general effect is very much like that of an open umbrella. From the solid spandril on the centre column rises a heavy octagonal post of oak, 16 in. diameter and 17 or 18 ft. high, morticed into which are eight heavy beams about 12 in. square, taking their other bearing on the solid wall over the buttresses. These beams, which are 33 ft. long, are supported by bent braces of all sorts of form and substance. The outer ones, which spring from corbels very low down, and only just over the spandril of the groin, have rent the wall in some places, and have occasioned a considerable outward thrust. These braces have become twisted and decayed; some of them have got out of bearing, and have allowed the strain on the centre pillar to become most irregular. The space between these eight main beams which I have described, is filled with seven heavy timbers 12 in. by 8 in. most injudiciously applied, the outer ends bearing on a heavy plate about 4 ft. above the point of the window, the thrust from which has much shaken the wall and injured the tracery of the windows; the other ends are wedged and skew nailed into principal binders. Nothing can be more injudicious than this construction; instead of throwing the weight of all these timbers on to the eight main beams, and so weighting the abutments, their load is thrown on the weakest part of the enclosing walls. The timbers are of oak and Baltic fir, indiscriminately mixed, and are generally in a pretty sound state.

The buttresses, which are of solid Chillmarke stone, are perfectly sound, and show hardly any symptom of decay or settlement; the intermediate walling is not so free from injury, the spaces below the windows showing indications of unequal settlement, from the greater mass and weight of the buttresses. The tracery of the windows is very much shaken, and the mullions have suffered considerably from the action of the weather and the corrosion of the iron bars. Internally the masonry is much injured, the exquisitely sculptured capitals, and the interesting series of scripture subjects commemorative of the life of Joseph having been shamefully mutilated by the Parliamentary Commissioners and their satellites, who quartered men and horses in these sacred buildings. The walls and niches bear evidence of having been highly decorated with colour and gilding, and there is still a strongly coloured ornament diverging from the bosses at the junction of the ribs. The stone seat running round the Chapter House originally occupied by the members of that body, is in a damp and perishing condition. The encaustic tile paving which covers the whole space of the floor is in a very unsatisfactory state, the colour much faded, and where the concrete foundation is carried round the walls, andthe central pier does not extend, it has sunk considerably below the original level. The windows have, alas, long lost the rich and glowing colours which, little doubt, originally added to the beauty of this exquisite room; the last remaining one having been taken down subsequent to Mr. Britton's survey in 1812. Although of the frailer material, wood, the old Chapter table (a most interesting relic) exists with less apparent injury and decay than even the walls which enclose it. The Purbeck shafts and capitals in the interior are, curiously enough, more decayed than the Chillmarke stone ones.

The centre shaft, of Purbeck marble 1 ft. 6 in. diameter, surrounded with its eight smaller ones, 4½ in. diameter, from which springs the groin enclosing the room, is still in good preservation, though it has been thrust out of the perpendicular an extreme distance of 4¾ in. to the east. The smaller shafts have perished considerably, and will require to be replaced with new stone. The simple groin which springs from this shaft has its ribs of Chillmarke stone, 2 ft. deep, and about 12 in. wide: the intermediate groin being of chalk, 1 ft. thick, in the upper surface of which is a coating of fine concrete or mortar, the underside being plastered, and the joints of the stone marked upon it. I believe I have nothing to add to the description of its present state, and I now pass to the consideration of its restoration.

The removal of the iron bars to which I have already alluded, and which have a very prejudicial effect on the appearance of this room, was the first point to which my attention was directed, and this has naturally involved a difficult and anxious consideration, resolving itself however into this one point: Whether the abutment now offered by the buttresses, with the additional power of resistance they will gain by the whole weight of the roof being thrown upon them, instead of being scattered over the whole enclosing walls, is suficient to counteract the thrust of the groin itself; (for care will of course be taken that the new roof shall occasion no outward thrust). I was led to suppose that, in the Chapter Houses of similar form and construction to this one, as at York, Lincoln, Wells and Westminster, I might find precedent of some kind. The inquiry has confirmed me in my previous belief, that the one at Salisbury was the lightest in construction of this class. At York, the groining to the Chapter House is not less deceptive than that to the nave and choir of the Cathedral itself, being of wood, in one span, of 57 ft. diameter. Till lately, it was enriched with painting and gilding; it has, unfortunately, of late years, been much injured by that worst vice in architecture, being made to assume the appearance of a material it really is not. It has been plastered and jointed and coloured in imitation of stone. With a sort of prophetic dread of the march of desecration, the Rev. John Drake, one of the Prebendaries, presented a view in 1736, "lest time or other cause should destroy or deface this magnificent structure." The roof, which seems to be of very strange construction, almost without any attempt at the principle of continuous trussing, has at least the redeeming virtue of being held together by the tie beams. I have been unable to get an accurate section of this building, which, however, is not of much consequence, as it bears so little on the object of my inquiry. This Chapter House, which, I believe, was built in the early part of the 13th century, would probably have been a few years anterior to the Salisbury one. The child certainly was not unworthy of the parent. The Chapter House at Lincoln is not much more useful to me, the excess of strength in this case being more puzzling. The groin itself could never have required such buttresses, and we can only imagine that the original roof must have been constructed with some considerable degree of thrust, against which these immense flying buttresses were brought into play. The present high pitched roof, which was restored in 1800 (one of low pitch having usurped the place of its original one) must, if correct, occasion a considerable thrust. This Chapter House is a decagon of 60 ft. diameter, and is supposed to have been the first built in this country of polygonal form, a variation from the square and oblong, as at Bristol, Glos'ter, Durham, and Peterboro', supposed to have been suggested by the circular churches of the Knights Templars. The Temple Church being dedicated in 1185, being 15 years before the completion of the Lincoln Chapter House, Giraldus Cambriensis attributing it to Bishop Hugh, who died in 1200. It undoubtedly must be considered a very perfect work for so early an era. "St. Hugh was a native of Burgundy, and may have obtained artists or designs from his own country." That of Wells is an octagon of 57 ft. diameter, resting on a groined crypt, Its height is considerably less than that of Salisbury, but like it, the groin springs from a central column 3 ft. diameter, surrounded by 16 smaller shafts, just doubling the size of the centre shaft, and the number of smaller ones at Salisbury. At first sight, the great disproportion between the abutments of this Chapter House and that at Salisbury, seems unaccountable: but on referring to the plan of the groining, it will be found that this of Wells is much more elaborately groined, and that the proportion of the stone ribs is as 9 to 3, 9 ribs springing from each buttress at Wells, 3 from each at Salisbury, naturally adding considerably to the weight and thrust even if the intervening groin was not heavier. I am not aware of the material used for this purpose. I believe chalk is not a material found in that part of Somersetshire: it is in all probability of stone instead of the lighter material. And in these causes, I think, the apparent discrepancy between the abutments at Wells and Salisbury may be satisfactorily accounted for. I do not know the exact date of the building. In feature and general detail it is of the same century as those I have alluded to; although in all probability it is subsequent to them. Whether it has gained in effect by reduced height and lightness, I must leave to others to determine.

The Chapter House at Westminster, the last I shall speak of, is of octangular form, and was a "remarkable instance of lightness and richness of ornament." It was built in the reign of Henry III, probably about 1250. As at Wells there is a crypt, the groining of which is of excellent workmanship. I believe that this building, in its original form, must have more closely resembled the Salisbury one than any of those I have referred to; apparently of similar height and width, its groin was originally supported by a central shaft having eight smaller shafts surrounding it. The walls are not of greater thickness than those at Salisbury; and the projection of the buttresses (where the flying buttress was not introduced) is as nearly as possible the same as at Salisbury. These apply to those on the north-east, north-west, and two to the west, where the cloister joins it. What the character of the original stone groining was, I believe there is no history remaining. Nor is it known exactly how long the monks held it, but in 1377 the Parliament held their sittings there, the crown having undertaken its repairs (well fulfilled) and it was so used till 1547, when Edward VI gave St. Stephen's Chapel for this purpose. It was then occupied as a place of deposit for exchequer records. On the 4th March, 1705, the House of Lords memorialized the Queen (Anne) to have it put into repair, and this is stated to have been done soon afterwards by Sir Christopher Wren, though I know not where are the existing traces of such repair.

The springer of the groin still remains over the central shaft, and the boarded floor rests on the old encaustic tile.

With the exception of this last instance, my consideration of the polygonal Chapter Houses has led to little satisfactory result; and if it were not that I fancy there is to be traced in each, good cause for the variations we find, I might become a convert to Mr. Gwilt's belief: "That the investigation of the equilibrium of arches by the laws of statics, does not appear to have at all entered into the thoughts of the ancient architects; experience, imitation, and a sort of mechanical intuition, seem to have been their guides. They appear to have preferred positive solidity to nice balance: nor have they left us precept or clue to ascertain by what means they reached such heights of skill as their works exhibit." I think if Mr. Gwilt had remembered the Chapter Houses of Westminster and Salisbury, he would have made them exceptions to his rule, and have allowed that at least they have worked as close to "nice balance" as in these examples they could well do.

Having failed, then, to discover, in these works of similar form and coeval date, any positive rules which could be a guide in determining the question of sufficient abutment, I endeavoured to find, in the works of those who have written on the theory of arches, some actual rule which I could reduce to practise, applying to this case. In this search I have not been very successful. The works of Peyronnet, Rondelet, Gautier and other foreign writers on arches, apply generally to bridges and other forms of vaulting rather than to groining as practised by the early Gothic architects; and that their abutments would not apply in one case is not very surprising when it is remembered that "rib pointed vaulting," composed "*ex lapide et topho*," has invariably the actual rib thinner than the uniform thickness of the Roman vault; and that the panels of the groin (the principal part in superficial quantity) sometimes does not exceed one-ninth the rib in thickness. A reference to their sections shows how light is the construction of Lincoln and Salisbury Cathedral as compared with that of St. Paul's, so much vaunted for the mathematical science it is said to display. The naves of St. Paul and Lincoln are the same height and width; the piers of the towers are double the diameter of the shafts in the latter, and its continuous wall exceeds in thickness by one-half the wall and buttress of Lincoln. Nor have I found anything in the works of Ware, Hutton, Mosely, Gwilt and others, which actually bears on this case. In the work of Durand, an old French writer on arches, a curious problem is laid down to determine the abutment of an arch, which, if not based on the soundest laws of statics, is at least ingenious and plausible, adapting itself to every form of architecture; the French engineers, I am informed, rely upon it to a great degree. I was so pleased with its simplicity, that I determined to test it by an experiment on a large scale. Having to construct the clerestory wall of a church, which was 50 ft. high, to the wall plate, with semicircular arches springing from columns 2 ft. 3 in. diameter, at a height of 18 ft. 6 in. from the ground, and abutting against a pillar, (of the strength of which some doubts were entertained,) I had formed in brickwork, to a quarter the full size, an arch of this description, retaining only as an abutment the width which this problem gave. The arch was loaded (in proportion) to the full height of the 50 ft., and no deduction was made for the openings of the triforia or for the clerestory windows, which in the original, would much reduce the weight over the crown of the arch. This experiment was made in a foundation of very questionable nature; it was carried up in mortar, and the centres were struck within an hour or two of its completion. This arch stood perfectly, and until the period of its being taken down, some weeks afterwards showed no symptoms of weakness. Having more abutment than this problem called for, and taking into consideration the reduction of weight effected by the openings I have alluded to, the clerestory walls were completed, as originally intended, and stand perfectly. This, then, is the most theoretically practical rule I have found, and has confirmed me in the belief that the vault of this Chapter House, would stand perfectly with the abutment it has. It will be found that the width of the abutment, at the level of the springing, is in the case of Salisbury, about one-fourth the span of the groin itself. That at King's College Chapel, Cambridge, although of a much flatter and more thrusting arch, has the thickness of the abutment only 3⅞ times the width of the arch.

Trinity Church, at Ely, has a stone vault of segmental form, which has the abutments only one-fifth of the span of the arch, that arch being of a very flat and thrusting form. Of these most complex theories of the arch, so seldom brought to bear on individual cases, and so seldom accordant, one is almost inclined to say with La Fontaine—

> "Quand on l'ignore, ce n'est rien,
> Quand on le sait, c'est peu de chose."

Unfortunately this discrepancy in theory extends itself to data given as the result of practice and actual experiment, and adds infinitely to the difficulty of arriving at anything like a satisfactory result in inquiries of this kind. As instances, I may state that Rondelet, a French writer of much celebrity, gives a force of 5000 lb. on the square inch, to crush a piece of oak, and upwards of 6000 lb. to crush fir; whereas Mr. George Rennie, in his elaborate and detailed experiments, found English oak to crush with 3860 lb. to the inch, and fir with 1928. The result of all experiments on wood, however, go to prove that the resistance increases in a much higher ratio than the mere area of the material.

Mr. Rennie found Portland stone to crush with 1284 lb. to the square inch. Messrs. Bramah, in their experiments in 1837, found 1020 lb. crush it; whilst a central stone shaft at Anjou Cathedral, which is considered a remarkable specimen of lightness, bears only 500 lb. to the square inch, though calculated by Mr. Gauthy to be equal to the resistance of 3470 lb. to the inch.

It is probable that few experiments were made actually on the same data, the stones are not of equal quality, the wood unequally seasoned; and when we remember that oak timber loses 30 per cent of its weight in seasoning, these differences are to some extent explained.

Believing that one sound practical opinion would avail more in this case than any theory, I have sought the opinion of those members of our profession, and of those of the engineers, in whose judgment on such points I have the greatest confidence, and they have without one exception confirmed my belief, that if the outward thrust of the roof is removed, these ties may be taken away. I had the benefit of the opinion of Captain Dennison, (Government Engineer at Woolwich,) who examined the whole building with me most carefully, and who fully concurs in this view of the question. We tested the upright lines of all the outer buttresses, and we found that with very little variation, they had all gone outwards, from the perpendicular, between 3½ and 4 in. to the springing line, even those immediately adjoining the staircase and cloister walls, where naturally the abutment is greatest; proving, as we think, that this must have been the effect of one uniform thrust, when the centres were first struck, and the whole groin took its bearing. We found the iron bars slack, hardly any of them being strongly in tension.

The centre pillar has gone over towards the east considerably, to the north-east 3⅞ in., to the east 4⅝ in., and to the south-east 3⅞ in., an injury we believed to have been much more caused by the irregular thrust of the heavy roof than by any action of a groin, which from its abutments having all equally decayed, must have been nearly "in equilibrio." The stone ribs show hardly any trace of the necessary contraction and expansion which must have taken place when this pillar went over; and the chalk groin shows no settlement that gives cause for alarm. Having then satisfied myself as far as possible of the practicability of removing these iron ties, we propose to shove up the centre column, these timbers having been brought to their bearing (the weight they have to carry being 115 tons). I propose to take down the present central shaft, with its eight surrounding ones, to plumb a perpendicular line from the centre of the octagonal stone above the capital, and from this centre to carry up, on the old foundation, the central pillar, making good, with Purbeck marble, such ones as may be found to have perished. This foundation is composed of concrete of the best description, and evidently laid before its reputed father, Sir R. Smirke, could have introduced it into this country. This effected, and the groin left to its proper bearing, (the iron ties still being untouched,) I propose to take off the present heavy roof, and in its place to substitute, as I strongly hope, the high pitched one, the feet of the principal rafters being laid into cast iron shoes, held together, or rather in their places by eight wrought iron tension rods, 1½ in. diameter, having an eye at the end nearest the centre, into which the suspension rod (thickened at its lower end to 3 in. diameter) would fall, and hold up the tension rods. This roof, if adopted, would render unnecessary the piece of timber now resting on the centre column. The sprandrils of the groin I propose to fill to the height shown by the red tint. That this was the original form of roof, I believe there can be little doubt, a view in which I have been confirmed by Mr. Pugin, who has carefully studied this Cathedral, and who speaks most confidently to the point; to suppose it otherwise, would be to imagine that in this building they had thrown overboard the vertical spirit of the Cathedral roof, and of all roofs of that size of which we have any trace. Having satisfied myself that the further perpendicular weight which would by this means be thrown on the buttresses, in addition to that of the groin, could have no crushing effect, the weight each buttress would have to carry being 62 tons, which distributed over the area of each, gives a weight of 59½ lb. to the square inch; whilst the capabilities of Chillmarke stone (taken at four-fifths the lowest given for Portland) would require 823 lb. to the inch to crush it. The centre shaft bears 1000 lb. to the square inch. Rondelet says "there can be no danger in making stone bear one-third the weight which would crush it;" it is therefore fair to suppose there can be none in giving it one-fourteenth; and in this calculation I have made no allowance for the increased tenacity afforded by an increase of superficies. This risk being avoided, the additional resistance thus afforded to the thrust of the groin by the weight above, would be considerable. Of the value of this heavy superstructure, Sir Christopher Wren was fully aware. In his report on Salisbury Cathedral, he says, "As for the vaults of the ailes, they are indeed supported on the outside by the buttresses, but inwardly they have no other stay but the pillars themselves, which as they are usually proportioned, if they stood alone without the weight above, could not resist the spreading of the ailes one minute."

Should, however, the Chapter (whose consent to any plan must be obtained) object to the high form of roof, and require the new one to retain the pitch of the present one, and not to rise above the parapet, their decision must be final, and in that case I should propose to adopt this roof, which though simple enough in its construction, has at least this advantage over its predecessor, that it causes no outward thrust.

In either case lead would form the covering. The roof being made perfect, and all defects in the external masonry having been made good, I propose gradually to loosen the nuts which are now attached to the iron ties, watching most carefully if any fresh thrust follows. Those bars I propose to re-introduce above the groin and immediately under the roof. They would form a perfect tie at this level, and if unluckily any accident or failing shall take place in the cast-iron shoes or tension rods of the roof truss, these bars would then come into play, and would prevent the effect of any lateral thrust. The internal stone work we hope gradually to restore. The stone seat and step running round the Chapter House will be taken up, cleaned and re-laid, making good with new stone. Under this seat, it is proposed to form a flue in brickwork, into which would be introduced from a stove, to be built under the stairs, a current of warm air, having vents through, and stone ornaments on each face of the octagon, thus keeping the building free from the damp which now disfigures it.

It is proposed to relay the whole floor (containing 236 yards) with encaustic tile paving, of similar design and colour to those now existing; and instead of their being laid on the earth as at present, which has tended to make the floor damp and irregular, I propose to have a thin bed of concrete made with water lime formed over the whole surface not occupied by the foundations.

The plastering to the soffit of the groin, which now exists, is in a defective state, cracked and discoloured. It will be repaired and recoloured; and as the chalk groin is of rude and irregular surface, it perhaps will be desirable to reline it as it now exists, restoring the present coloured ornaments which now diverge from the bosses.

I have now only to allude to the windows. It is years since the last window of stained glass existed in the Chapter House. It was then taken down and used in the restoration of some of the Cathedral windows. If there ever existed a building in which colour was an essential ingredient, it is this; and I have every confidence that if the restoration, to which I have already alluded, can be satisfactorily carried out, that it will not be a very distant period before these windows will be filled with glass, whose colours shall be not less rich and harmonious than those which originally decorated this interesting building.

Iron Ships.—"*The Iron Queen.*"—We find that iron, as a material for ship-building, is fast gaining ground. For steamers, iron has been a favourite for some time past; and there is not now one wooden steamer building at this port, while we observe there are two iron ones, of the first class, nearly completed, and, we understand, contracts are made for the building of three more. We are also now satisfied, that the only objection to sailing vessels of iron, namely, the getting foul during a foreign voyage, is completely removed.. This is proved by the result of two voyages of the *Iron Queen.* This barque, 350 tons register, left the river Tyne in February 1842, with 124 tons of coals for Havana; from thence she went to Mobile for a cargo of cotton for this port. She has now completed another voyage, from this port to Galveston, in Texas, carrying 300 tons of salt out, and a full cargo of cotton home. She has been in the Graving dock, where she was visited by many persons, and she is found not to have strained a single rivet, although she struck heavily on Galveston Bar. There is no appearance of corrosion, the red lead being fresh on the plates; and neither shells, barnacles, nor any foulness, was on her bottom. This desirable result is caused by the simple application of a compound of tallow, bright varnish, arsenic, and brimstone, which effectually destroys marine, vegetable, and animal substances. *The Iron Queen* was built by Messrs. John Vernon and Co., of Aberdeen, and has proved very creditable to their skill as builders. The surveyors for Lloyd's here are so well satisfied that there is no corrosion that they have classed her A. 1.—*Liverpool Albion.*

IMPROVEMENTS IN LIVERPOOL.

[The following observations by Mr. Rosson, were made upon a paper lately read at the Liverpool Polytechnic Society, by Mr. Holme, on the improvement of Liverpool; we regret that we have not been able to obtain Mr. Holme's paper.]

Mr. Rosson said, that in compliance with the invitation of their respected president, he rose to make some observations on the very interesting paper just read by Mr. Holme. Architecture had been one of his favorite private studies for the last twenty years, and he had often lamented, during that period, to see the little progress which this great commercial metropolis of the north-west of England has made in exhibiting good specimens of construction. This was the more remarkable, when the vast means of private individuals, and the funds placed at the disposal of the corporation, were taken into account. Reference had been made to the noble models of architecture left by the ancient Greeks, whose remains which had escaped destruction still excited the admiration of every traveller who looked upon them. The Parthenon, for instance. Let us inquire by what means that transcendant work of architectural genius was raised? Why, it was raised because Phidias, the prince of sculptors of antiquity, had a Pericles for a patron, and by the influence of the illustrious sculptor, Ictinus and Callicrates were employed as architects, though under the controul of Phidias. But, independently of the good fortune of the Athenians in having a Pericles to judge and guide them in the application of high art, the Greeks had a mode which he (Mr. R.) would strongly urge the people of Liverpool to adopt, now that public competition had become the rule to guide them in their choice of the artists who were to execute from time to time the works that were to adorn their great city. The practice among the ancient Greeks was to call upon a number of distinguished architects to send in designs by a certain day, and when they had all been exhibited, to leave to the artists themselves the choice of the one that was to bear away the palm. This was by giving each artist *two votes*: one in favour of *his own design*, and the other for the *one he thought the best* among the compositions of his rivals. The best of the whole always turned out to be the one approved by the majority of the *second votes*, as a reigning beauty, at a public ball, is always considered by every handsome girl in the room decidedly the handsomest present, *after herself*. (A laugh.) Thus the wisest of the people judged and appreciated artists, and artists themselves judged and appreciated each other, in the face of all Greece, assembled on great public festivals. And in modern times, a very remarkable instance of public justice occurred at Rome, in the pontificate of Benedict XIV. That distinguished pontiff invited a competition of designs for the improvement of the Piazza del Popolo, in which our, then, young countryman, the late Mr. Harrison, of Chester, entered the lists. The judges selected a Roman design: against the decision the famous Piranesi protested. His holiness caused the drawings to be re-examined. The consequence was that the judgment was reversed, and young Harrison received the gold medal. He (Mr. R.) lamented to say that that distinguished architect, the greatest since the days of Wren and Gwynne, chose afterwards to bury his fine talents in the little obscure city of Chester, instead of settling in London, and correcting the bad taste of Soane, Nash, and others. When a resident in the Temple, he (Mr. R.) had joined with his hon. friend, the member for Scarborough, Sir Frederick Trench, in the efforts made about fifteen years ago to construct the Thames Quay. The society, however, they then formed, though under the immediate protection of his late Royal Highness the Duke of York, and, indirectly, under that of the crown itself, could not accomplish their great object, though aided by many distinguished noblemen, gentlemen, and merchants, and by "the unaffected grace," and elegance, and talents, and powerful patronage of the late all-accomplished Duchess of Rutland. They, however, managed to erect some good buildings, amongst which must be named Stafford House, in the Stable-yard of St. James's Palace, the finest nobleman's town residence in the empire. He (Mr. R.) was cognizant of every stone laid in the construction of that edifice. The staircase, the finest thing in London was formed on the model of that of Versailles; and the house, with the recent additions of the present noble proprietor the Duke of Sutherland, formed decidedly the finest private palace ever erected in England. Finding, however, that public taste was not ripe for the quay, they intermitted their labours, as he observed, fifteen years ago: but he was happy to say that they had resumed them recently, with every expectation that, with the aid of the government, and the awakened taste of the age, and the labours of his friend Charles Barry, at Westminster, on the new Houses of Parliament—all those combined, he thought, would at length enable them to achieve the object of all their vows, and give a new character to the banks of the noblest river in our domestic empire. At the period referred to, when they (the committee) were busily engaged in their efforts, and publishing drawings, of which they were very proud, and were gradually drawing the attention of the London public, the elder Mr. D'Israeli entered their council-chamber, and astounded them with the information that they could not establish any claim to originality—that he held in his hand a book that set at rest and put the extinguisher upon all their claims as *exclusive authors* of the grand schemes they were projecting. He (Mr. R.) had referred to a "great unknown" of the name of Gwynne. Had any gentleman present ever heard of his name? He dared say not; and yet Gwynne was one of the greatest architects that this or any other country had ever produced; the book Mr. D'Israeli brought was the work of that illustrious architect, called "*London and Westminster Improved*," 1761 or 1763. Every public improvement that had been made in London or Westminster, during the last thirty years, was down in that book, with this especial difference, that Gwynne's designs are infinitely better, exhibited greater taste, elegance, judgment, imagination, and resources than the works actually carried into execution. For instance, a bridge was suggested in the very place where Waterloo Bridge now stands, under the name of "*George the Third's Bridge*," with approaches on each side the Thames, infinitely finer than those erected. Regent-street appears under the name, I think, of "*Great George-street*," with elevations much superior to those actually existing—the bold cornice, the stone balcony, the harmony of parts, the solidity, in fine, which all our streets want, were there to be found sketched, giving a new character to London as it then existed. But that great man, whose talents were appreciated by Edmund Burke, Dr. Johnson, and the great men of the Literary Club formed by the great lexicographer, had the misfortune to be born forty years too soon. The times were not germane to his labours; public taste, from want of education, was not ripe; and his work, which deserved immortality, and would have obtained it in a better age, fell, still-born from the press. His name would almost have been lost, had it not been kept alive by a reference to him made by Boswell in his Life of Dr. Johnson. But to return to the improvements of our "dear native city." Liverpool—for, though not a city *in law*, she was a city *in fact*,—he (Mr. R.) entirely concurred with his friend Mr. Holme, in all the observations made in his very excellent lecture; but he must confess that when he came down to the bottom of South Castle-street, he was much disappointed and surprised to see him make a *back somerset*, as it were, and avoid all mention of the *New* Custom-house. He (Mr. R.) never looked upon that building but with sorrow and disappointment—sorrow, that that erection completed the destruction of the finest inner harbour formed by nature in the kingdom (and in this he was confirmed by the opinion of the greatest engineer now living, whose name was another name for science in civil engineering), and disappointment, that so noble an opportunity of displaying architectural genius had been thrown away, by the erection of a building whose composition was full of bad architectural grammar, and whose vastness and solidity alone relieved it from absolute contempt. It was faulty in composition and in position, and its bad material excited the amazement of every one who knew that the vigilant jealousy of government was generally exercised with reference to the materials wherewith every specimen of architecture, civil or naval, was constructed. Look (said Mr. R.) at the basements of the columns. No geologist, deserving the name, would consider such material *stone*, but rather a *conglomerate* of sandstone in its primitive formation, full of cracks, and threatening to fall to pieces: the columns in *ten pieces*, instead of *two*. The joints will be the first part of the building to decay: posterity will have to replace them sooner than the present generation imagine. Walking round, you may almost thrust your thumb into holes filled up with clay and rosin! Alas! all this arose from irresponsibility, and the absence of competition. It was a bad thing for the architect himself. His (Mr. R's.) friend, Charles Barry, competed with all the rising talent of Britain both for the Houses of Parliament and the Reform Club-house,—the finest private palace, for its purpose, perhaps in Europe. To return to the Custom-house. In point of composition—the utter want of distribution of light in the rooms and corridors produced a "darkness visible," which, independently of its perpetual inconvenience in a place where so prodigious an amount of business is transacted, gave the whole the appearance of the gloomy chambers leading to the catacombs of the dead. Indeed, said Mr. R., I have long denominated it "The Tomb" of the inner harbour of the port of Liverpool. Mr. R. proceeded to say,—"I speak this in sorrow: but just censure is the tax which all public servants must pay, especially that portion of them who have been largely endowed by the public press, and have not returned their money's worth in public service." But he would now turn to a more pleasing subject. He begged to congratulate the society on the prospects before them. Liverpool had at length obtained the aid of an architect, whose talents were of a high order. He had been recently introduced to him in London—was delighted with his designs, and pleased to find him so young a man. Liverpool had nothing, as yet, but her *docks* to exhibit to the stranger: those would pass muster with the greatest engineers. But they had now to look forward to the erection of a *Place* (as the French called it) that would form the capital of the city, containing a street and courts of justice of surpassing beauty. That would be the era from which posterity would date the commencement of an architectural style worthy of the second commercial city in the empire, and, consequently, in the world; and he felt justly proud, encouraged, and animated by the approaching triumph.

BLASTING OF THE ABBOT'S CLIFF AT DOVER.

Another of those remarkable engineering operations which have already attracted the public attention, in connexion with the South Eastern Railway, took place on Tuesday, April 18th, at a distance of about three miles to the westward of the town of Dover. In order to afford an outlet to the Abbot's Cliff Tunnel, and a platform on which the rail could be laid down between that and the Shakspeare tunnel, it became necessary to remove a portion of the projecting cliff. From the success that had attended former operations of the kind, and especially the recent blast at Rounddown Cliff, it was resolved to remove it by the aid of gunpowder.

The surface of the cliff acted upon by this explosion lay to the westward of the Rounddown Cliff, and its remaining cliff forms the face of the terminus of Abbot's Cliff tunnel. It extended 300 feet in length, and the height of that portion which was directly acted upon was 200 feet. The object of the operation was to slice off, as it were, a large portion of this surface, so as to make that which was before rugged and uneven, and which projected far too much in the way of the proposed line along the side of the cliff, perfectly flat and smooth, and fit to afford a sufficient platform for the road to be laid down upon, and to prepare the terminus of the tunnel. The "slice" to be removed varied in thickness, according to the extent to which the surface projected beyond that which would be convenient to the operations; at some points it was 60 feet, and at others 30 feet, and the quantity of powder introduced at the different parts was, therefore, proportioned to the thickness of cliff to be removed, regulated, of course, by the degree of resistance which, from the greater or less nearness of the surface to the chambers in which the powder was deposited, would be offered to the action of the powder. The quantity of powder in each chamber was calculated according to the line of least resistance. Cubing the line of least resistance, one-half the number of feet is the number of ounces of powder used. The arrangements made for the introduction of the powder and the simultaneous ignition (if possible) of the different charges were simple, and, at the same time, ingenious in the extreme. There were altogether 100 barrels of powder, or 10,000 lb. This quantity was distributed in various proportions in 15 different chambers, at nearly equal distances. To form these chambers the rock was perforated at those nearly equal distances, and the different proportions of powder were introduced on Saturday last, and "tamped up" close. There were two separate lines of these chambers of powder, and therefore two series of charges; one being near the top of the cliff, about 200 feet from the summit, the other about 100 feet lower down. Thus a space of about 150 feet from the bottom of the cliff remained altogether untouched by the explosion, that being required as a platform for the road to run upon at the entrance of the tunnel. The apparatus for igniting these different charges was placed to the eastward, about 2000 feet from the nearest, and about 500 feet from the furthest chamber. It consisted of six batteries of 20 plates each, and by an ingenious invention of Mr. Hodges, the assistant to Mr. Wright, the resident engineer of the line from Ashford to Dover, they were all fired simultaneously. Simple as the invention is, it is not so easy to describe it on paper. Suppose a triangular skeleton chair; what would be the seat of it is suspended by a common string at the distance of about an inch or more from a framework beneath (resting on the legs of the chair), in which are fixed the batteries and connecting wires. Immediately under the string which suspends the other portion of the battery is placed a circular trough, in which there is a "blue" light. Through this light is passed a fuse, 12 feet long, and taking some minutes to burn down. This fuse was fired by Mr. Hodges, who had time to get away from the spot before the string was burnt. The moment the string was severed by the flame, down went the upper framework, the voltaic action was performed, and the electric fluid communicated to the wires. These wires were two, one for the upper, the other for the lower range of chambers, each extending the whole length of the surface to be operated upon, and attached to them were other supplementary wires communicating with the chambers of powder. The ends of these additional wires were of course formed in the usual way, with a piece of platina wire affixed, which on being made red hot by the electric fluid ignited the gunpowder in what are called the bursting charges—small portions of powder in cases surrounding the ends of these wires, which again immediately fired the larger quantities of powder contained in the different chambers.

Thus within a few moments after the ignition of the blue light, the upper framework of the skeleton chair above described fell down, the voltaic action was completed, and in almost an equal period of time the explosion was effected. And yet how remote to all appearance the connection between the burning of a short piece of string (a foot long) and the fall of that immense mass of cliff!

The operations at the Rounddown cliff were carried on under the advice of General Pasley and Lieutenant Hutchinson, who also took a great interest in the proceedings on the present occasion; but the whole of the arrangements for the explosion of to-day were under the controul of Mr. Wright, the engineer, assisted by Mr. Hodges, as already mentioned. As far as the practical effect of the operation was concerned all was successful; but as a mere sight the affair was unfortunate, in consequence of the thick fog that hung over the cliff, and made it impossible to see the actual fall.

At 4 o'clock, the hour appointed for the blast, many thousand persons were collected to witness it, but the thick fog obscured all. I took a boat, and approached as near to the shore as was allowed, but could see no more than the crumbling mass falling down into the water beneath with a sound resembling the roar of artillery heard at a distance, and the noise of the surge breaking on the sea shore. In respect of the noise created, this explosion differed from that at the Rounddown Cliff. There no noise whatever was to be heard, or scarcely any, and the mass of rock glided almost silently into the sea like a mighty wave; but in the Abbot's Cliff blast there was much more noise, and it was more prolonged.

Those who were on the cliff were sensible of a shock a few moments before the detached portions of the cliff fell. Explosion is an inappropriate term to use; for, in fact, as far as hearing is concerned, there is nothing of the sort; —the operation of the powder is internal, and the effect only known by the fall of the fragments. Mr. Hodges, the assistant engineer, fired the fuse in connection with the battery. He had four minutes in which to get away, but had calculated that he could run down the ladder in two and a half. He was the last person who left the range of the batteries.

Beside the multitude of persons collected on the cliffs and on the adjacent shore, the sea was covered with boats of all sizes and shapes. There were also two large steam-boats filled with visitors.

Although in consequence of the thick fog or mist the spectators were deprived of much of the gratification which such a sight would have afforded, the operation, in a scientific point of view, was held to be decidedly successful. All the chambers of powder were ignited simultaneously (or nearly so), and the immense mass of disturbed chalk and earth fell slowly and equably into the sea. The exact results, however, cannot of course yet be ascertained. —*Times.*

ROYAL ACADEMY.

Professor Cockerell's Lectures on Architecture.

(From the Athenæum.)

Lecture VI, and last.

Proportion, and the application of its golden rules, as they affect the external forms of architecture, had occupied the latter part of the preceding lecture; the *αναλογια* of the Greeks, delivered to us by Vitruvius, that analogy, by which all the conformations of artificial bodies were derived from natural bodies, seemed to be a principle of obvious importance and utility to the architect, and should be attentively considered.

It appeared that the animal kingdom furnishes clearer lights for our guidance than the vegetable, because organized nature was more constant in her proportions, and enabled us always to re-establish the whole from a part; thus the hand of a Grecian statue, of the Hercules, the Apollo, or of the Venus, or a fragment of any one of the Grecian orders of architecture, enabled us to restore the whole; indeed, the proportion by aliquot parts by a modulus, a principle of the Greeks, as explained by Vitruvius, lib. i. c. II, lib. iii, c. I, was still practised in India, and seems founded in organized nature.

Not so in the productions of the vegetable kingdom, fragments of which would never enable us to comprehend the whole: however indebted to this part of the creation for the graces of ornament, and various essential analogies, architecture found a less sure guide of proportion in this than in the animal kingdom: in fact, all architecture so derived was anomalous, as the Egyptian and the Gothic, in which no fixed laws of proportion have ever been applied or attempted. Columns or supports might be from five to fifty diameters in height, and were only bounded by possibility. The stunted pollard, the spreading cedar of Lebanon, the aspiring poplar, or the attenuated cane, were extremes equally at the disposal of the architect.

But that guide, which the face of nature furnished to the architect for his external forms and proportions, was wanting for the internal—as of areas, squares, courts, and open places; or of internal capacities (height as well as area); as of temples, halls, apartments, &c.; in these we must appeal to the relations of reason, purpose, and convention.

Vitruvius (lib. vi. c. 2, 3, 4, 6, lib. v. c. 1, and c. 2.) gives us the experience of the ancients on this important subject. The Greek forum, says he was a square, but the Roman was three by two, because the gladiatorial, shows were exhibited there; courts should have the proportions of five by three (the favourite of the learned Palladio), sometimes three by two, or sesquialteral, or the diagonal of the square will be the length. He lays down the proportions of all the apartments of the Greek and Roman house: atria, alæ, tablinium, and peristylium, triclinia, œci, exedræ et pinacothecæ. He does not, however, establish any *principle*, and his rules are wholly empirical. But the great Alberti, not content without a principle, adopts the Pythagorean doctrine of universal harmony, and agreement between sounds and numbers, namely, that what pleases the ear pleases also the eye; he lays down, therefore, his harmonic proportion, in which Blondel, Ouvrard and others have followed. The notion of musical proportions is common, and has occupied many ingenious minds already versed in that art. Describing St. Peter's, Byron, in this feeling, observes

> Vastness which grows, but grows to *harmonize*,
> All *musical* in its immensities.

Alberti was the first also to establish the rules of arithmetical and geometrical proportions (lib. ix. b. 3, 4, 5, 6), applied to all the varieties of areas and capacities. He is followed by Palladio in the arithmetical and geometrical rules, lib. i. c. 23.

It is a comfortable conclusion to the practical architect that the empirical rules of Vitruvius, the harmonic, the geometrical and arithmetical rules of Alberti and his followers, agree in the main, so that either may be adopted without material deviation from correctness; but the neglect of these rules, in which lie that hidden charm that every one must be sensible of when examining a finely proportioned room, has been common of late years, as if the principle were of no value; the zealous student therefore should carefully note that consent of the ancients and the most illustrious masters of the moderns, here set forth: and he will soon learn devoutly to repeat the denunciation of the Hindu Vitruvius (Ram Raz, Asiatic Society, 1834, p. 15), "Woe to them who dwell in a house not built according to the proportions of symmetry."

It is true, that the climate of this country and our habits do not often permit the finer Italian proportions; thus the arithmetical rule of proportion, common with our greatest masters, in our best mansions, 36 by 24, should give us 30 feet high to the vault, but we commonly limit it to 18 feet. To correct the defect of lowness, so frequent with us, the illusions of perspective painting, after the admirable Pozzo, may well apply; but even the arrangement of the trabeation and plaster enrichments, offer to the ingenious architect, versed in perspective, many resources for the increase of the apparent height, and for the attainment of an artificial proportion. But a manufacturing people are prone to carpets, rugs, curtains, gilded frames, and mahogany furniture, while the low ceiling is a sheet of paper stretched like a drum, at most of a neutral tint, of indurated fog, with a gilt moulding: while the artistic Italian opens a window of perspective in his ceiling, through which a canopy of poetry and distance delights the eye, and deceives the understanding; but the floor is paved with tiles.

Again, in our modern churches, a ceiling, 60 by 80, has often been fearlessly stretched in one unbroken surface of plaster, in defiance of the fine examples of Charles's and Queen Anne's churches, in which a cove, after the Italian manner, has the effect of reducing the ceiling, and of rectifying the proportion in the simplest and most graceful manner. The student should well reflect on this important field for architectural skill and effect. He may be a good builder and cheap, but he can have no pretensions as an artist who throws away his time and his character in such condescensions as this mechanical employment of his talent implies.

The rules hitherto referred to, have the beautiful for their object. Beauty in architecture depends, amongst other causes, especially on the exact and graceful proportions of the parts and of the whole. But the sublime depends upon other causes, in which rules cannot prescribe; to the latter not only the rules of the former do not apply, but they are destructive of it. If the beautiful resides in the proportionate, it would appear that the sublime often resides in the disproportionate. The principles and the rules of beauty and sublimity are distinct. If we stand under an arch of London Bridge, the vaulted soffite, so vast and extended, sustained from such distant abutments, produces a kind of sublime; no doubt aided by its comparative lowness. The Pantheon is inscribed in a cube, its height equal to its diameter; no one standing under its prodigious cupola has ever denied its sublimity. But when that same Pantheon is raised into the air (in equal dimension) at St. Peter's, it may have become beautiful, but has lost its quality of sublime. When Byron apostrophizes the Pantheon, he feels the peculiarity of its merit:—

> Simple, erect, severe, austere, sublime,
> Shrine of all saints, and temple of all gods,
> From Jove to Jesus, spared and blest by Time.
> Looking tranquility!

As the dome of the Pantheon is raised at St. Peter's into a proportionate height, at the expense of its sublime, so the nave (nearly twice as wide as that of St. Paul's Cathedral), also raised proportionately, loses all effect of magnitude; and the common and universal observation is, that as respects this important effect the architect has laboured in vain; and the work stands self-condemned.

The noble poet coincides with the received opinion, and is obliged to supply by poetical moonshine that dignity and interest which it was his object to give to the Vatican. He says—

> Enter, its grandeur overwhelms you not,
> And why? it is not lessened; but thy mind,
> Expanded by the genius of the spot,
> Has grown colossal; and can only find
> A fit abode wherein appear enshrined,
> Thy hopes of immortality!

Sometimes this failure has been attributed to its proportion, which (from its justness, it is said) takes from its magnitude; a criticism at once the most severe and just that can be. In fact, no increase of a proportionate object will ever give it magnitude and the sublime; these depend on extraordinary relation and excess of parts and proportions.

Some years ago a French giant, upwards of nine feet high, exhibited himself in London, but so just were his proportions that no one would give credit to his dimension, till they stood beside him; he was therefore accounted a kind of fraud, and the exhibition failed. But had he been disproportioned, his head small, his shoulders high, and his members excessive, he might have succeeded, even had he been a foot shorter. Had the nave of St. Peter's, 77 feet wide, been 90 feet high only, instead of 145; or if we were to suppose a stage raised mid-height and place ourselves upon it, we should be sensible of its vast latitude, and the effect of magnitude would have been produced as under a bridge. The Barriere de l'Etoile, from the same reasons, though as large as the front of Notre Dame—the arch itself 48 by 95, equal to the height of the nave, but of ordinary proportions and great simplicity of parts and members—loses its effect: the *arc monstre* is glorious to the *grande armée*, but not to the arts of their day; and is infinitely less artificial in its combination that the arches of St. Martin and St. Antoine, designed by the accomplished Blondel.

If, then, the architect can obtain latitude, he should seek to carry out its effect by quadrate and comparatively low proportions; but if he adds altitude to his latitude, he loses his expense and pains, and he may find too late that half his dimension might have attained the same effect; since *proportionate magnitude* defeats itself.

But as extreme latitude gives the sublime, so does its opposite extreme of altitude: in Cologne and Beauvais, the naves of which are three and a half diameters in height, though scarcely more than half the actual width of St. Peter's nave—limited, therefore, in their dimension to the usual cathedral width, yet nearly double the usual proportion—the sublime is completely attained; and disproportion again appears to be the efficient cause.

But the optical consideration of the visual angle in which these several proportions present themselves is exceedingly important. Thus to the spectator of the dome of the Pantheon, the visual angle is 95°, while the same dome raised into the air at St. Peter's is only 30°. In the nave of St. Peter's, the visual angle is 48°, that of St. Paul's Cathedral is 37°, while the vault of Cologne is only 22°. Since then the effect of magnitude is measured by the number of degrees in the visual angle, the architect will advert to this consideration as of extreme interest.

We come, then, to the important conclusion, that the sublime and the beautiful are to be found in the proper adjustment of proportions, rather than in dimensions; and we may infer, that no increase of scale to the beautiful will ever make it the sublime.

But the sublime is of rare occurrence: the use, however, to which these reflections may be turned by the practical architect, under limited means, is remarkably illustrated in the Casino at Chiswick, where the very circumscribed area of the rooms is compensated by their extraordinary height, and the accomplished Lord Burlington has given a nobility to very small apartments which no one could believe on seeing the plan alone, without visiting that elegant work.

Magnitude is the great object and result of design, and this quality is only to be attained by the fine adjustment of relative proportions in magnitude and order. Architecture consists in magnitude and order (says Aristotle), το γαρ καλον εν μεγεθει και ταξει εστι. (Poet. p. xi. s. 4.) The works of man, compared with those of nature, display our insignificance. The pyramids, seen in the clear sky of Egypt, or St. Peter's at Rome, are proverbially disappointing to the first gaze of the beholder: it is only after he has instituted comparisons and admeasurements that he becomes sensible of the greatness of these human efforts—and his memory will supply him with many instances in which objects of very inferior dimensions have surpassed them in impression of magnitude upon his mind. It is plain, therefore, that art alone can produce the full effect of magnitude, and to this the architect should direct all his skill: the ancients will be found consummate masters in this as well as in every other department of our art. It is, indeed, a fine art which enables the accomplished artist to raise ideas of magnitude and grandeur of composition on a piece of paper no bigger than your hand; while a less able one shall cover a vast canvas without executing any comparable notions. Worthy of all inquiry and solicitude is such an art, for it is the whole art of design and proportion. Pliny cites a statue of Hercules, so small that it might be lifted by the hand, which, however, conveyed more grandeur, magnitude, and strength to the mind of the observer, than a Colossus would have done. How great must have been the science of the master! and if, with such small means, he could affect the mind with these impressions, how great the economy of cost and material to the employer!

Burke, whose notions, however, of proportion are vague and erroneous, says admirably on this point (sec. x.)—"A true artist should put a generous deceit on the spectators, and effect the noblest designs by easy methods. Designs which are vast only by their dimensions, are always the sign of a common and low imagination."

In the last lecture it was attempted to show that magnitude, breadth, and proportion of parts were best found in inequalities; but the consideration of magnitude, as respects composition of the whole, seems to depend on other principles: first, it appears that, to make a great whole, there must be many parts; secondly, to appreciate that whole, the point from which it is permitted to be seen should be eusynoptic, namely, so contrived as to fill the angle of vision of 45·0, and occupy the whole retina with multiplied impressions fairly and agreeably presented.

With reference to the first proposition, it may be observed, that in a young tree bursting from the ground, two or three branches with upward tendency grow from the polished bark; the subdivisions are few, and we may count the leaves. By and bye, with age and maturity, the bark becomes rough and corrugated, the base is surrounded with excrescences and roots, which, partly above the ground, indicate the hold it has on all the surrounding space; the branches now shoot out at right angles with the bulky stem, each limb becomes a tree, the subdivisions of these are infinite, and, in all degrees of size and proportion, the leaves are countless. So the young animal, simple in parts, and smooth, expanding with age and strength, develops features and subordinate parts never dreamt of before; furnished and complete, the measure and fullness of strength and beauty is at length filled up. So in architecture, the tetra-style portico can never look large, though, in St. Peter's, the columns have eight feet in diameter. The Hecatompedon, burnt by the Persians, was not inferior in the scale of its parts to the present Parthenon, but Ictinus judged that, by increasing the number of parts—making that octo-style which had been hexa-style only—greater magnificence would result.

The temple of the giants, at Agrigentum (hepta-style) was the largest Doric of antiquity, but to give it all its value, a number of new features, never seen before, accompany its increased growth and vastness. It is raised on a platform of many steps, a base of novel design surrounds the columns, and these vast masses themselves, each a tower of thirteen feet in diameter, built of many stones, told by its many parts and its elaborate construction the cost and grandeur of the undertaking. So the columns at Pæstum have twenty-four instead of the usual twenty flutings; in short, examples are infinite to show that, to convey the full effect of real magnitude, an artificial magnitude must be superadded, or it is lost labour.

Gradation and repetition of features of the same general resemblance in various sizes, the major and the minor, are main sources of magnitude; the artist will see, in the satellites surrounding the planet Jupiter, the best reason for the title of the Father of the Gods; the western towers of St. Paul's give magnitude to the dome. The same principle was to have been applied to St. Peter's, but the western towers fell down. In the admirable church of the Salute at Venice, the minor dome over the high altar, and again the still smaller towers accompanying this, are foils to the great dome. Byron admirably enforces the number of parts:—

> "Thou seest not all; but piecemeal thou must break,
> To separate contemplation the great whole;
> And as the ocean many bays will make,
> That ask the eye—so here condense thy soul
> To more immediate objects, and controul
> Thy thoughts, until thy mind hath got by heart
> Its eloquent proportions, and unroll
> In mighty graduations, part by part,
> The glory which at once upon thee did not dart."
>
> *Childe Harold*, c. iv, v. 157.

So Palladio (as already remarked) characterized his style by the interpenetration of the larger order by a smaller.

In decoration we are careful to put a small scroll in juxta-position to the larger, to give its full effect; and so the painter, to give size to his principal figures, interposes women and children in various gradations; the wreath or swag which shall contain flowers or fruit, all of the same size, will be mean, or look like a string of onions; the whole secret of proportion and whole purpose of magnificence is attained, by satellites, and by gradation of the major and the minor.

With reference to the second proposition, the consideration of the point of view of architectural works, the ancients, as has been already observed, were consummate masters, and cannot be too carefully studied. The labour of the architect is vain, if he miscalculates the point of view, and the picture which he is to present on the retina of the spectator. As well might the painter consent to a bad light for his work, as the architect be careless on this point. The *genius loci* will insist upon a peculiar composition; each position requires its own adaptation; we should have proper things in proper places. A design good in one place may fail in another, and the unskilful approach and point of view may ruin the best scheme. It is not enough to be right, but to show that you are so: the "*faire valoir*" is a fine economy which runs through the architecture of life, as well as of every step in brick and mortar. The architect must be well versed in this part of optics: the synoptic, the eusynoptic, the *deceptio visûs*, should be his constant observation; like a skilful general he must manage and manœuvre his masses to impose upon the spectator, and by their skilful disposition he may often gain that ascendancy which his real forces may not warrant. A familiar instance of this is seen at St. Paul's, and often practised upon the green-horn mason, who visits London for the first time. Of the two orders which decorate the exterior, the lower one forms the great order of the interior, in the same precise dimension; but the angle of view in the interior being so much larger, the spectator is persuaded of its larger dimension. The roguish cicerone engages the novice in dispute on this question, enforced by a bet, which on proof is always to his disadvantage and the penalty of his pot of beer.

Sometimes accident does more for us than wit. St. Paul's, constrained, and crowded amidst narrow streets, produces on the unsophisticated a magnitude and interest which would be lost if the pedants had their way, and large areas and terraces were to expose it from Farringdon Street and the Thames.

While considering magnitude, we must not forget that (the most difficult of all) which arises from greatness of conception—a quality which every one habituated to contemplate fine buildings, must often have been impressed with. But much more the ingenious architect, who in his practice has had opportunities of comparing his own design with those of others more able than himself, and still more in canvassing the various modes in which a work might be performed, will remark the difference between one mind and another. He will find all the moral qualities of the artist exhibited in his performance. "By their works ye shall know them;" greatness of soul, or contractedness of spirit, a folly or a vice, the specious, the clumsy, the refined, the honest, are written in characters quite legible to those who have learnt to decipher the language of design.

We might show the character of Wren in the lineaments of his work—sublime in his mathematical attainments, clear, original and comprehensive in his combinations above all men; but in his exterior unobtrusive and timid, small and elaborate, concealing the art (as Nature does) revealed only on our nearer examination to our wonder and delight. We plainly see "the Nestor of Athens, not only in his profession the greatest man of that age, but who had given more proof of it than any other man ever did; he was in a manner the inventor of the use of mechanical powers; and they record of him that he was so prodigiously exact, that, for experiment's sake, he built an edifice of great beauty, and seeming strength, but so contrived as to bear only its own weight—so that it fell with no other pressure than the settling of a *Wren!* But such was Nestor's modesty, that his art and skill were soon disregarded, for want of that manner with which men of the world support and assert the merit of their own performances: and for want of that natural freedom and audacity, necessary in the commerce of life, his personal modesty overthrew all his public actions."—Parentalia, p. 341.

In the works of Jones we see the beautiful and specious, the sensual beauty of the tasteful artist, but no mathematics, no sublime combinations of structure, but generous, and free, and highly ornamental, we discover the director of the masques of the splendid court of the Stuarts—the "Marquis Would-be."

In Vanbrugh we have the dramatist throughout; his theatre and scenery are everywhere, imposing with a pompous grandiose, the spectator is at first captivated, till he peeps behind the scene, and the illusion vanishes.

In short, it is plain that the architect must have moral as well as intellectual qualities, to acquit himself duly of the high charge intrusted to him; and no argument can more effectually convince the student, that in ordering his studies he must first order his own character and conduct; and that nothing can come from him of great and noble, unless from a pure fountain and a well-regulated stream. We must endeavour to sustain that rank in society which both sacred and classical antiquity have assigned to the architect (see Isaiah, c. iii. v. 1, 2, 3; and Cic. Off. p. 42.)

But an important principle in the æsthetical as well as in the real ends and purposes of our art is solidity, the result of equilibrium between the forces of gravity. Nothing can be beautiful which is not strong, or is not adequately strong for its purpose. The impression of duration is indispensable to that satisfaction and repose which the mind seeks in a well-ordered work of architecture. According to the simple notions of the ancients, it was the essence of the grandiose and beautiful. The temple of the eternal was to breathe the spirit of eternity—strong in its entire structure, it was to be strong also in its component parts, its "great stones." Energy, menta and physical, and stability, were the expressions most desired in architecture; voids were to be above voids, solids above solids; the area even of the supports, and the incumbent weight (orthographically considered) in most instances of the finest temples are, or approach to, equality.

To this end the whole composition of the edifice was pyramidal, the sides being inclined (as has already been observed) in every style of architecture known to us. The quoins and piers of the angles which inclose the work are larger than those towards the centre; and we may be sure that the expression of strength and duration given to a building is often of itself sufficient for beauty, without other adventitious ornament; as we may also be certain that the want of this quality cannot be repaired by any expedient which the architect may apply. In fact, the qualities of solidity and equipoise impose on the understanding the same awe and conviction with reason, justice, and truth; as inspiring that security, stability, and peace, without which all is flimsy conceit and vain ambition.

But this rational propensity is sometimes in jeopardy from the love of the marvellous and the exhibition of skill in the artificer, from whom, while we deprecate the hazard, we cannot withhold our applause; and if assured, either by the nature of the material or the quality of the structure, of the security the mind demands, we are easily reconciled to the wonder. But this temptation is often a severe trial to the ambitious architect; and without a sober taste, chastened by modesty and reason, it may be often more than he can resist.

We delight in the suspended arch of a bridge or in the enormous vault which covers the Pantheon, or the baths of Caracalla, or the Temple of Peace. We are reconciled to those of the Gothic cathedral, so long as their stone props or buttresses continue to perform their duty. Not so in the grove at the east end of Salisbury Cathedral, which, like the banyan tree, seems to be composed of pendants from the roof, in different dimensions, rather than columns to support it; beautiful, indeed, but so fragile that the blow of a stick or the movement of an awkward visitor would put the whole fabric in peril. If, instead of a friable stone or marble, these shafts were made of brass, the mind would relapse into that security which is ever the first requirement of our art.

The love of the marvellous is dangerous; exaggeration is the first sign of a mind indifferent to the value and beauty and sufficiency of truth, and the surest sign of depravation of judgment. Truth must ever be the best foundation of taste, and can alone be constant and enduring—

> Rien n'est beau que le vrai; le vrai seul est aimable!
> Il doit regner partout, et même dans la Fable.
> De toute fiction, l'adroite fausseté,
> Ne tend qu'à faire aux yeux briller la vérité.
>
> *Boileau*, Ep. ix., v. 43.

The Egyptian, the Roman, and sometimes the Greek, indulged in the gigantic, with a view to the expression of a prodigious energy. But the middle ages were prone to the marvellous, surprise was the great scope of the Gothic architect. Æsthetics were not, indeed, likely to have been studied under the education to which the mind at that time had access. Miracles infatuated the understanding; superstition was the foundation; a dominant hierarchy was little communicative of the lights of science it possessed. The poetical vein received its chief aliment from the east; our scholars brought home from Cordova the Arabian taste for excess and hyperbole. The chastening counsel of a Locke, a Newton, or a Bacon, were wanting to regulate that exuberant and uncultured fancy, and that enterprising skill which the practical experiments in building promoted at so much cost and zeal in those ages.

The two styles of building, till the 15th century, were termed *more Romano*, in semi-circular arches, which followed the old basilica model of St. Peter's and St. Paul's, and *more Germano*, in which the pointed arch was employed after the 13th century; it was in the latter taste that the greatest works were executed.

However great and admirable, in many respects, the specimens which have been left us by those able practitioners, it is not believed by the most competent judges that theoretical science was cultivated to any extent. From Cesare Cesariano, the architect of Milan cathedral, and one of the earliest translators of Vitruvius, doubtless one of the most learned architects of his day (1524), we may learn something of the principles which guided the middle ages, which were full of the mystical terms of the pseudo-science of the Freemasons. They consisted of a series of triangles or pyramids, no doubt in allusion to the triune, which guided the plan, elevation, and section; see D'Agencourt's architecture, plate 46, in which the sections of Milan and Bologna cathedrals illustrate those doctrines. The minster at Bath appears to have been built after this theory (1503) by Dr. Oliver King, who was a skilful architect and politician, and had been employed in France to conclude a peace with Charles VIII., and who, therefore, would be acquainted with the most approved art of that day on the continent.

The middle age church was wholly founded on superstitious associations. According to *more Romano*, it was enough that the plan described the cross, the universal symbol in "hoc vince." But according to *more Germano*, the Saviour himself was to be figured; the choir, therefore, was inclined to the south, to signify, that "he bowed his head and gave up the ghost," John, c. xx, v. 30; and there are few cathedrals in which this deflection in not remarkable. The nave represents the body, and the side, which "one of the soldiers pierced," (John, xix. 34), considered to be the south as the region of the heart, is occupied at Wells by a chantrey, at Winchester with the chapel of William of Wyckham, and is constantly the pulpit from which the faithful were reminded "to look on him whom they had pierced," Zech. xii. 10: who "was wounded for our transgressions," Isa. liii. 5. For the same reason the south was considered the most holy: the Old Testament was represented on that side, while the New Testament, and the local or national Hagiology, was placed to the north. The same superstition still gives value to the south side of the churchyard for burial. At the head of the cross was the chapel of the Virgin, at the Fountain of Intercession with her son. At the foot, the west end, was the "Parvis," supposed by some to be a corruption of "Paradis," that happy station from which the devout might contemplate the glory of the fabric, which was chiefly illustrated in this front and from whence they might scan the great sculptured picture, the calendar for unlearned men, as illustrative of Christian doctrine and of the temporal history of the church under its princes and its prelates. Three great niches leading into the church, the centre one often above forty feet wide, were adorned with the statues of the apostles and holy men, who "marshal us the way that we should go;" in front the genealogy of Christ, the Final Judgment, the History of the Patriarchs, &c.

The details, indeed, display the degraded state of the fine arts, and of course, of the artists themselves, in the quaintness and disproportion of the sculpture. But extending our indulgence to the performers, regarded in illiberal times only as workmen, we shall admire their native genius, struggling with their moral condition, often on the verge of dignity and grace in execution, and in point of conception frequently reaching an elevation altogether original. It must be confessed that the continental churches, especially those of Amiens, Rheims, and Paris, surpass the magnificence of our own cathedrals, both in the extent of plan by their double ailes, as well as by their height. But it may be questioned whether a more complete and correct picture of Christian doctrine and dispensation, and Christian history, is to be found anywhere than in Wells Cathedral.

But the same want of cultivated judgment which is apparent in the æsthetical of the arts of the middle ages, is traced also in the imperfection of their statics and sterentomy, in which again solidity is sacrificed to superstition. The indispensable figure of the cross is a striking example. The arches of the nave in the northern basilica, found their abutment abundantly in the western termination, which was commonly fortified by prominent buttresses (called by the early commentators of Vitruvius, tetra-style, or hexa-style, according to their number); but at their eastern termination, towards the lofty pillar of the transept, no such abutment existed. And though the pointed arch was eminently calculated to obviate lateral pressure, yet the smallest failure of foundation or superstructure, threw so much weight against these pillars as to occasion them to bend. To counteract this, and secure their stability, the principle of that age, of "pondus addit robur," namely, the weighting the pillars of the transept with a tower or spire, was resorted to very commonly; but this often increasing the evil, the last disfiguring remedy, the construction of a reversed arch between them, was employed.

Similar criticisms apply to all parts of the middle age architecture, mixed, however, with redeeming excellencies of peculiar skill hitherto unsurpassed.—See sections 1 to 8 of Wren's surveys, in the "Parentalia." 264 to 309.

The fifth of those principles of Vitruvius, which the Professor had attempted to illustrate, was Decor, usually considered to refer to that important part of architecture, ornament; but our author rather appeared to refer to consistency of character, fitness of style and ornament to the Deity, and the purpose or the rank to which the work might be dedicated, quoted in the preceding lecture. But as no part of the art required a nicer judgment, tact, and reasoning than this of character and special physiognomy, so was none more commonly transgressed in many modern buildings; and a stranger might be conducted to some of them, and defied to guess whether he beheld a library or a town hall, a church or a music room, a theatre, a prison, a brewhouse, or a floor-cloth manufactory, a gentleman's mansion or a union workhouse.

Appropriateness and fitness of character is the special recommendation of all the great critics, from Aristotle to Pope. If, says Horace, to a horse's neck a human head is joined, or a female head and breast should terminate in a fish, you will despise the painter; or if upon the stage you exhibit the graces and the levities of youth, hashed up with the manly strength of middle life or the rigour of old age, the audience would yawn, and at length overwhelm you with indignant hisses. It is, in fact, the significance and appropriateness resulting from the coincidence of use and beauty, the one the explanation and plain result of the other, which we adore in the works of Nature, and which the great artists have best known how to imitate in theirs.

Sir C. Wren remarks on the Temple of Peace—"It was not, therefore, unskilfulness in the architect, that made him choose this flat kind of aspect for his temple; it was his wit and judgment. Each deity had a peculiar gesture, face, and dress hieroglyphically proper to it, as their stories were but morals involved; and not only their altars and sacrifices were mystical, but the very forms of their temples. No language, no poetry can so describe Peace, and the effects of it in men's minds, as the design of this temple naturally paints it, without any affectation of the allegory. It is easy of access, and open, carries an humble front, but embraces wide; is luminous and pleasant, and content with an internal greatness, despises an invidious appearance of all that height it might otherwise boast of; but rather, fortifying itself on every side, rests secure on a square and ample basis." On the Temple of War, he says, "As studiously as the aspect of the Temple of Peace was contrived in allusion to Peace and its attributes, so is this of Mars appropriated to War; a strong and stately temple shows itself forward, and that it might not lose any of its bulk, a vast wall of near 100 feet high is placed behind it; (because, as Vitruvius notes, things appear less in the open air;) and though it be a single wall, erected chiefly to add glory to the fabric, and to muster up at once a terrible front of trophies and statues, which stand here in double ranks, yet an ingenious use is made of it, to obscure two irregular entrances," &c.

The German Moller, who is as true and as accomplished an artist as any of modern times, on this point says, "On comparing the elevation of the Merchants' Guildhouse, at Mentz, with the church of Oppenheim, which was finished in the same year, we see how anxious the ancients were, and how well they contrived to impart to every building its peculiar character. Just as the merit of historical painting, and of every art of design, (without which all the rest is valueless,) consists in the importance and peculiarity of its character, so they are principal requisites in buildings, whenever the latter lay claim to the appellation of works of art. In the church at Oppenheim, all the parts are lightly towering up, so that the eye of the spectator in the interior is involuntarily raised, and the elevated richly ornamented windows, and slender aspiring pillars, promise from the outside already a beautiful and sublime interior. But in the Merchants' Guildhouse, the whole exterior announces at once an object very different from that of a church. The few and small windows are easily closed against fire and robbers; and their battlements again, with their projecting canopies and angular enrichments, clearly show that the destination of the building is to preserve and to protect. And in the same way as the main forms correspond with the object of the structure, so likewise do the ingeniously designed ornaments. On the pinnacles or battlements are the figures of the emperors and electors in full armour. The emperor, who, at that time in alliance with the electors, had confirmed the commercial union of the cities on the Rhine, and taken them under his protection, appears with them here, as the guardian and bulwark of the house. In the midst of the princes, is the figure of St. Martin, the patron of the city, dividing his cloak with his sword, to give it to the poor. Thus, the leading forms announce the destination and solidity of the building; the figures of the princes, the protection it enjoys; St. Martin, that beneficence which ought to be the attendant of wealth; and the Virgin Mary with the infant Jesus, over the entrance, the higher safeguard which the Divinity grants only to the *just*." Thus says the accomplished Moller.

It is a fine observation of Aristotle, that "a noble building without ornament is like a healthy man in indigence." Competence, if not wealth, must be added for the accomplishment of his happiness.

The sculptor's art affords the noblest ornaments to the architect. By his aid, the expression which he has been labouring to give by other associations, and which before was mute, or scarcely audible, becomes *parlant*. Sculpture may be called the voice of architecture. Unhappily a Protestant country, with the holy fear of image-worship, discourages this generous and most essential art; and perhaps the want of character complained of in architecture may be mainly attributed to this proscription.

But the carver and the decorator are highly serviceable to the architect, not only as multiplying images for the delight of the eye and the explanation of the subject, but as greatly magnifying the scale of the whole by these means, and giving value and distinction to the plainer features. Our mistress Nature is prodigal in ornament, and the expression of every animal and vegetable is increased by a texture of endless detail spread over the whole surface of her works.

Finally, Distributio, the οικονομια of the Greeks, the sixth principle, is explained by Vitruvius, drily, as economy in the use and cost of materials; but doubtless the great masters from whom he borrowed, considered economy, in the larger sense, as the adjustment of means to the end; as the wise and fine thought, contrivance, and supply, of all the requirements and appliances of the building art; in which the highest intelligence is displayed; such, indeed, as by that figure of speech which designates great subjects by small titles, applies to the *Creator* himself that of the great architect.

The diligent observer of architectural works will find the greatest strength combined with the least material, beauty united with use, and resulting from it, exact equilibrium, provisions for the accidents of time and climate, selection of materials best adapted, in short, a prescience of every want and consideration: throughout the contrivance admiration almost sublime is occasioned; we feel that the work has, as it were, been self-created by the influences and the wisdom of nature, and as if the architect had only followed her instructions. "I am not," says the heifer of Myron, "the work of Myron—he only delivered me from the marble" in which I was inclosed.

Having thus reviewed the theoretical rules handed down by Vitruvius from the Greeks, as far as the limits and means permitted, the Professor proceeded to offer some observations to the students, with reference to their future advancement, which it was the object of these lectures, and the ardent wish of the members of the academy to promote.

First, with respect to drawing, which was the very language of the art, it was extremely important that the distinction between the painter and the architect should be clearly understood. He deprecated the vain ambition of making pretty drawings, especially on a small scale, as effeminate and uninstructive; as also of pretensions to aërial perspective, which was a separate art. Much time was commonly occupied in this captivating study, which was wholly irrelevant, and at the expense of that valuable time which should be employed in the more essential accomplishments of the art and science. It might, indeed, improve the hand, but not the head; of which the architect had so much need. Drawing after the manner of painters had undoubtedly been an abuse and misdirection.

The orthographic drawing or elevation was conventional: it represented the proposed building from an immeasurable distance—the object being to define those proportions and profiles which constitute the merit of the work—such lights and shades as should more clearly display these forms, and show their relief where necessary; but whatever disturbed these paramount objects, as colour, or such cast shades as might confuse the profiles and pretend to illusion, were impertinent.

Perspective, in the most accurate delineation, was, indeed, a most desirable accomplishment, but it should be wholly linear, assisted with one tone, or two at most. Sciography should be used with great reserve, since the harsh outlines of cast shades were apt to disturb the form and outline; and the finest architectural perspectives, those of Pozzo especially, left them softened and undefined on this account. It was certain that such had been the practice of the great Italian masters, specimens of which, by the hands of Sansovino, (the front of Sta. Maria, at Florence, in the possession of Woodburn,) of Michael Angelo, Raphael, and others, and especially the designs for Whitehall, by Inigo Jones, the Professor had exhibited in a former course. Exquisite perspective, proportion, and profile were more scientific, difficult, and much more profitable to the student. The coloured picturesque was a pandering to a depraved taste, and it was a duty to inform the public on this head, and lead them to the appreciation of the true intent of architectural delineation. The draftsman should be habituated to a large scale, and a manly drawing of profile and detail, such as a builder would comprehend and work from. The Professor exhibited a specimen of the architectural drawing of the actual school in Paris, which, though not wholly to be approved, as being rather too minute and elaborate in effect, still showed a more careful attention to outline, and a better system than used by ourselves.

The architectural room in the annual exhibition was at great disadvantage in the neighbourhood of the splendours of the sister art; the vain attempt at vying with her productions in architectural drawings, had both corrupted our style and exposed the utter futility of the attempt. The true course would be a closer adherence to the province of the architect in a more correct delineation of profile and proportion, and in the most accurate linear perspective; a tasteful employment of these resources would probably more effectually uphold the interest of that room than any other means that could be devised.

Constant observation and travel were essential to the architect; but the interesting objects of our own country should be seen before those of others. Much time was often lost in foreign travel by misdirection and the dangerous novelty of the student's position.

In examining architectural works, the student should bear in mind an important rule of criticism, which was, to account in precise terms, for the motives of approbation or dislike which he might experience. By applying a just expression on all occasions, he would soon cease to take one thing for another—the beautiful for the sublime—quantity for quality—cost for magnificence—and either of these for proportion or fitness—ornament for art. He would learn to apply characteristic terms to every gradation, quality, and style: and so, by degrees, he would form a just and discriminating taste.

In an art and science essentially referable to association, this discrimination was peculiarly necessary: the emotions arising from sight, like those from music, would often be found irrespective of the intrinsic merit of the performance, as loyalty in hearing "God save the Queen," union and patriotism in the "Marseillaise." Often patriotic, historical, and romantic associations will blind us to forms and styles, otherwise both unfit and unworthy our age; often quantity, extent, and quality of material would impose that approbation which ought only to be accorded to elegant and just proportions; elaboration would often usurp the praise which was due only to a well-ordered work.

To hide by ornament the want of art,

should not deceive the experienced critic; and the painter "who would make his Venus *fine*, not knowing how to make her *beautiful*," would be ranked as he deserved. The discernment of merits rather than defects will be found more difficult, and much more profitable, because those we shall appropriate, while the latter are only to be rejected. Such a habit will exercise the better qualities of the mind, and lead to originality. The works of men who have long enjoyed reputation, should be the peculiar objects of our critical examination; they will seldom be found frauds; the inquiry will commonly justify their fame, and like the conversations of original inventors, they will reveal secrets which can else hardly be discovered.

The antiquary should be distinguished from the architect, and he should be careful to separate the available experience, from research into the curious and obsolete.

The student was recommended especially to cultivate that manly independence of mind which became a thinker, and the leader of an art; he should have a settled distrust of fashion; although he would find himself sometimes constrained in some measure to bend to it. Those "who live to please, must please to live;" he should, however, courageously but respectfully remonstrate.

There were two rocks, which the art was expressly liable to: the first was the presumption of absolute novelty; the second, the indolent and servile imitation of former styles. The latter was the peculiar vice of these times throughout all the civilized countries of Europe. Grecian, Gothic, Byzantine, Italian, Revival, French, were indifferently employed. There was no attempt at a style which should express to future ages the century in which we live; and posterity will be at a loss to recognize in the buildings of our day, that character which a country great and glorious at the present period, the bulwark of civilization, the arbiter of the world, and the great exemplar of political government, morals, and useful science, should impress upon its architectural productions. Shall it be said that this great people, original and free in other respects, adapting and expanding itself in an unexampled manner to times and improvements, was stationary, or rather retrogade, in the arts alone? That though science and capital and mechanical skill were daily furnishing new engines for our art, with prodigality, that our invention alone in these walks of genius was at a stand? that our skill as artists was the only deficiency in the march of our age? That they crudely adapted the models of ancient Greece to modern London, the sunny palaces of Italy to the foggy atmosphere of England; the niched and canopied architecture of a religion peopled with images of saints and martyrs, sibyls, angels, and holy men, to a Protestant religion, which, admitting none of these, must leave the niches and the canopies *tenantless*, like well-guilt frames adorning an apartment, the *pictures* being omitted: the pride and pomp of heraldry, armorial shields and crests, to an age in which chivalry was exploded, and quarterings had dwindled to insignificance? What should we say of Harry the Sixth, if, instead of that admirable and most original chapel of King's College, at Cambridge, he had limited his artists to the style of the Conqueror, or any other imitation; or if Henry the Seventh had concluded on carrying on the style of the cathedral of Henry the Third, and so on, saving all further trouble of invention and criticism, should we not contemn their poverty of spirit and negation of mind? Would not the historian, the artist, and the tasteful observer, have to deplore the absence of that internal evidence and hieroglyphic character of the times, which adds such a relish to the architectural remains of our fair and beloved country?

But let us suppose that either of these monarchs had been enlightened by the art of a Raphael or a Michael Angelo, or by the sculptures of a Phidias, which he might even affect to appreciate and to be proud of; and that we should learn by historical record that he had said—"We are so anxious to carry out the style of former days that we shall shut our eyes to those excellencies of sculpture and of fine art, and force our artists to copy the obscenities and senseless carvings of those barbarous times; simply that we may carry out the imitation of the style in all respects."

Restoration, indeed, is a different consideration, and the happiest result of this taste is, that we reinstate, for centuries to come, those venerable antiquities to which we have so many reasons of attachment. The restoration of the Palace at Westminster may find under this consideration a sufficient apology. But for works altogether new such a system of imitation is not reconcileable with our pretensions to genius and enlightenment; and it does appear that there is in it a vice of mind or of industry for which posterity will visit us. Such an indifference as to choice of styles indicates, in fact, an absence of culture and perception of the really fit, and beautiful, and great—a state of mind which, in religion, politics, or morals, would be accounted fatal to improvement, and the sure forerunner of every heresy. D'Agencourt attributes to this spirit of imitation under the Emperor Hadrian the decline of taste in Rome.

The learned in Paris deplore it not only under this apprehension, but as the imposition of anachronisms on posterity, and as the falsification of the pages of history, in its most interesting and characteristic traits. "Have we not," as says Isaiah, "a lie in our right hand?"

It is very important that the merits of that question should be debated in a candid spirit, and that the true grounds of a style should be investigated by the rules of sound criticism; as how far architecture has ever been and should be the picture in which all the discoveries of mechanics, of materials and of industry, are to be exhibited and recorded; and whether the successive changes of style have not been chiefly owing to the progressive discoveries and improvements on workmanship, materials, and convenience. How far the combinations of this art are capable of displaying the intellectual character of an age and people, and what should be the just bounds and limits of association, authority, and imitation.

Finally, let us never forget the pregnant saying of the great Schiller:—

> The artist is the son of his time;
> Happy for him if he is not its pupil;
> And happier still if not its favourite.

In conclusion, the Professor expressed the gratification he had felt in the attention paid by the students to this course of lectures; not as it reflected upon himself personally, but as it gave the strongest possible evidence of the ardour and assiduity with which they pursued their studies: for he could with great sincerity assure them that, amongst the achievements of a very long period of singleness and devotion to his profession, he should consider that the most glorious, which had contributed to the instruction, and warmed the enthusiasm of those rising talents destined perhaps in future times to adorn and illustrate our country.

INSTITUTION OF CIVIL ENGINEERS.

Feb. 7.—The PRESIDENT in the Chair.

"*Description of a Drawbridge at Bowcombe Creek, near Kingsbridge, Devon.*" By George Clarisse Dobson, Assoc. Inst. C.E.

This drawbridge spans one of five openings in a stone bridge, built across a navigable branch of Salcombe Harbour; it is in one leaf, 15 ft. 9 in. wide, and 32 ft. long, from out to out, supported upon a cast iron shaft or axle, placed 7 ft. 6 in. from the inner end, working in the abutment pier, which is built hollow to receive it, and thus the part within the axle end acts as a counter weight. To the centre of the end cross-beam of the counter part, a chain is attached, and after passing over cast iron sheaves in the masonry of the face of the abutment, is coiled on a drum fixed on a horizontal shaft, carrying on one end a pinion, worked by a rack, attached to the piston of the hydraulic press; by this means, motion is given to the shaft and drum, and consequently to the leaf of the bridge. Balance boxes are hung to the counter end, by which the shutting is regulated. The struts for supporting the leaf, when raised, are also thrown in and out of their places by a rack and pinion. The hydraulic press used for opening and closing the bridge, is simple in its construction, and the whole works so easily, that a female can open and close the bridge in about 15 minutes without difficulty. The fresh water used for the pump is contained in a cistern beneath, and seldom wants replenishing, as it is returned into the reservoir every time after being used. The bridge was designed and erected by Mr. J. M. Rendel, about 12 years since, when he was engaged in improving the turnpike road in the south of Devon. The expense of repairing, oiling, packing, &c., since its erection, has averaged under 7*l.* per annum, including a small salary to a neighbouring millwright for occasional inspection. The communication is accompanied by a drawing, showing a plan and sectional elevation of the bridge and the machinery.

ON FRICTION.

"*An Investigation of the comparative loss by Friction, in beam and direct action Steam Engines.*" By William Pole, Assoc. Inst. C. E.

In consequence of the comparatively recent introduction of direct action steam engines on board the steam vessels of the Royal Navy, the attention of engineers has been drawn to the advantages or disadvantages they possess, when viewed in comparison with those constructed with side levers. The object of this paper is to investigate the value of an apparently formidable objection which has been frequently urged against the direct action engine, namely, "that from the more oblique action, consequent upon the shortness of the connecting rod, the loss by the increase of friction is so considerable as to constitute a serious objection to this form of engine." After explaining to what extent mathematical analysis is applicable for determining the amount of friction, the paper proceeds to show that it may be satisfactorily used in the present case, as it is only the friction caused by the strain, or load, which is involved in the objection, and this is more adapted for theoretical than experimental determination.

The three general laws of friction, as established by the best experiments, are,

1st. That the friction caused by one solid body rubbing upon another, is independent of the velocity with which the rubbing surface moves.

2nd. It is also independent of the area of the rubbing surface.

3rd. It is proportional to the pressure upon this surface.[1]

From these it will follow, that if the pressure upon a moving body be multiplied by a certain co-efficient of friction (whose value is dependent upon the nature of the rubbing surface), the product will be the resistance from friction; and this multiplied again into any space the rubbing surface moves through, will give the amount of "power, work, or labouring force," expended in overcoming the friction through that space.[2] If the pressure upon the moving body be variable throughout its motion, the differential calculus must be employed, but the principle of calculation is still the same.[3]

The paper proceeds to deduce general mathematical expressions for the amount of friction on each bearing of an engine, by finding, first, by ordinary statical rules, the pressure thrown on each particular bearing by a given force applied to the piston, and then combining this with the space through which the rubbing surface moves. This is done for the beam engine, and for three modifications of the direct action engine. Equations are also added for the oscillating or vibrating engine, and for an arrangement in which the connecting rod is supposed to be indefinitely lengthened. The numerical values of the expressions for friction thus found, are then calculated for an engine upon each of these different constructions, supposing them to be similar in all other respects, having the cylinders 66 inches in diameter, with a length of stroke of 6 feet; and the results are shown in a table, distinguishing the friction of every bearing. From this it appears that as respects the friction caused by the strain, if the beam engine be taken as the standard of comparison—

The vibrating engine	has a gain of	..	1·1	per cent.
The direct action engine with slides	loss	..	1·8	"
Ditto with rollers	gain	..	0·8	"
Ditto with a parallel motion	gain	..	1·3	"

This difference being so trifling, it is contended that the objection to the direct action engine, on the ground of its alleged increased friction, has, when investigated, no adequate foundation.

Mr. Field believed that the paper was correct in its view of the comparative amount of friction of the two kinds of engines. He was of opinion that an excessive allowance for friction had hitherto been generally made in calculating their effective power. It was found practically, that when the pressure upon the piston was about 12 lb. per square inch, the friction did not amount to more than 1 lb. or 1½ lb. per square inch. This was easily ascertained by the indicator, when the engine was working without a load, but when loaded, he knew of no accurate experimental mode of showing it. At the engines of the Blackwall railway, the experiment had frequently been tried, by casting off all the load, and so regulating the steam, that the engines should make only the regular number of strokes per minute; the result had invariably shown about 1 lb. per square inch for friction.

Mr. Taylor confirmed the preceding remarks; it had been the custom formerly in large pumping engines to allow one-fifth for friction, but modern practice had shown that this was not necessary, particularly since greater precision had been introduced into the construction of all kinds of machinery.

Mr. Miller agreed that the friction of engines generally had been over-

[1] Poisson, Traité de Mécanique, 2nd edition, art. 456.

[2] If m = the co-efficient of friction, P = the pressure, and S = the space moved through, then the power expended = mPS.

[3] Let x be any space moved through: let X represent the variable pressure, expressed in terms of x, then the power expended = $m\int X\,dx$.

rated; he believed that as a simple comparison of the friction of the main parts of two kinds of engines, the results arrived at in the paper might be received as correct; but there were several other questions which must be considered, if it was intended to establish a general comparison between the beam and the direct action engines; this, however, he believed was not the intention of the author.

Mr. Murray contended that the second proposition in the paper, which assumed that "friction was independent of the area of the rubbing surface," although supported by Coulomb and the early experimenters, had been proved by Vince and others to be incorrect; it was natural to suppose that in proportion to the hardness and smoothness of bodies, there would exist a different ratio for the best proportion of surface to weight for every different body; if a surface carrying a given weight was of less than the due area, the surfaces would cut into each other, become rough, and thus increase the friction; on the other hand, if the surfaces were unduly enlarged, there must be a loss from the additional amount of friction caused by the extended surface. He conceived that the calculations in the paper must be affected by the incorrectness of the data upon which they were based. The simple mode of comparing the beam engine with the direct action engine appeared to be, to suppose two engines of the same length of stroke and diameter of cylinder; the proportions being good, it would be indifferent whether the power was transmitted through a direct connecting rod or through side levers; the cylinders, air pump, arrangement of parallel motion, &c., being supposed to be alike, the friction of these parts would be alike in all cases, and the comparison would be limited to the parts employed in transmitting the power from the piston rod cross head to the crank pin; both connecting rods have the same number of bearings, which in both cases travel with friction over nearly the same distances: it is allowed that the bearings of the shorter connecting rod have a larger amount of friction, and that from the greater angle it assumes, more friction is thrown upon all the bearings of the parallel motion, on account of the greater force required to retain the piston in a vertical position. To counterbalance the increased friction on these parts of the direct acting engine, allowance must be made in the beam engine for the friction of the beam centres and of the top and bottom necks of the side rods. The friction being directly as the distance moved through, and the distance in the side rod ends being so very small, it follows that the amount of friction must be very trifling. The distance travelled by the beam centres is greater, but it is not of importance, as it is the angular distance due to the vibration of the beam, measured on the circumference of the gudgeon. Under these considerations Mr. Murray was disposed to give the preference (if any existed) to the side lever engine. In a pamphlet[4] published in 1840, by Mr. John Seaward, it is stated that four-fifths of the whole friction of an engine were absorbed by the packings of the piston and air-pump bucket, by the slide valves and by the different packings or glands; consequently one fifth was due to the whole of the necks or bearings throughout the engine. Now on considering the large proportion of this amount of the friction that is due to the bearings of the main shafts, of the crank pin, and of the bottom end of the connecting rod, and of all those other bearings common to both sorts of engines, it must be evident that the total amount of the friction due to those parts in which a difference between the engines exists, must be but a small portion of this one-fifth. Taking one-tenth or ten per cent. of the whole power of an engine, as the amount of power required to overcome the friction of the engine itself, which was allowed to be ample, one-fifth of this would be two per cent., and therefore the degree in which either engine could surpass the other in the amount of friction, could only be, as already stated, a small portion of this two per cent. In comparing the efficiency of these engines, it would thus appear that neither could be said to possess advantages over the other, as regards friction, in such a degree as to be appreciable in practice, or to render the point of importance in a choice between the engines; and that if the one kind of engine had advantages over the other, they must arise from other causes than difference in friction. Having taken this view of the case with a supposed side lever engine, of the same length of stroke and diameter of cylinder as the direct action engine, if manufacturers varied in a slight degree from this proportion, it was for the purpose of obtaining a better proportion of stroke and diameter of cylinder, and consequently a better engine than the one supposed to exist for the purpose of making the observations.

Mr. Vignoles looked upon the second proposition assumed by the author, as being overthrown by the results of the experiments of Wood and others, as to the ratio of friction to the area of rubbing surface; and it was well known practically, that the application of various unctuous substances materially altered the amount of the friction. A certain proportion was requisite between the area of the surface exposed to the friction and the pressure upon it, to bring it within the general law. For practical purposes, he submitted that the law should be received with limitations.

Mr. Gravatt said, that even allowing, for the sake of argument, that the second proposition assumed by the author was incorrect, still as the paper was only a theoretical examination of the comparative friction of those parts of two kinds of engines, which were most subjected to strain, supposing them both to be of similar power and dimensions, equally well proportioned and constructed, and the same sort of lubrication of the bearings employed, he would contend that the circumstances being equal, equal results would be obtained, and that the conclusions arrived at by the author should be received as correct.

Mr. Pole observed, that the objections brought forward were important, as they referred principally to the fundamental laws of friction. He would first give some explanation respecting the communication itself. The investigation was commenced at the request of his late friend Mr. Samuel Seaward; it was originally intended to have especial reference to the Gorgon engine, but had subsequently been extended to others. The paper, necessarily containing much mathematical reasoning, could only be read in abstract, and might, therefore, have been partially misunderstood, both as to its objects and results. The object was, not to enter into a discussion of the whole question of the respective merits or defects of beam and direct action engines, but simply to ascertain the value of the one objection named.

The whole friction of an engine at work with its load upon it, might be divided into two distinct parts. 1st. The friction due to the engine itself, or such as would be produced by the working of the engine, if unloaded. 2nd. The additional friction caused by the strain consequent upon the load; for it must be evident that when the engine had its work upon it, the friction upon the bearings through which the strain passed, must be increased, and additional friction produced, beyond that which would exist when the engine was working without a load. The latter of these alone required to be calculated, and to this mathematical analysis was more peculiarly adapted. The friction of the engine unloaded, might be ascertained by the indicator, as described by Mr. Field; but as he had remarked, there was no practical method of finding what was the additional friction when the load was applied; indeed, it would be as difficult to find the latter by experiment as the former by theory.

He then explained the manner in which the amount of friction upon each bearing had been calculated, and engines of different constructions compared with each other. He had adopted precisely the plan suggested by Mr. Murray, namely, by taking engines of the same length of stroke and diameter of cylinder, supposing them to be equally well proportioned and constructed, and in equally good condition. But instead of assuming, as Mr. Murray had done, that there was somewhat more or less friction on any particular bearing, his object had been to ascertain what was its actual value. If it were impossible to measure the pressures and spaces moved through, an approximation might be received; but since these quantities were ascertainable, it was more satisfactory to obtain results deduced from them. The conclusions drawn from the paper accorded, however, with Mr. Murray's, viz. that "neither construction could be said to possess advantages over the other, in such a degree as to be appreciable in practice, so as to render the point of importance in a choice between them." The difference between Mr. Murray's process and that in the paper, was, that what the former only assumed, the latter endeavoured to prove.

Mr. John Seaward's pamphlet on the Gorgon engine had been referred to. The conclusions he there drew were more favourable to the direct action engine, but were derived, like Mr. Murray's, merely from approximate consideration, rather than from strict investigation. Mr. Seaward confessed, that the friction caused by the strain was difficult to be calculated, and had therefore contented himself with assuming, that those gudgeons through which the strain passed, had three times as much friction as was due to the others. He also assumed that the friction was proportional to the area of the rubbing surface, a principle which no experiments had ever shown. On these grounds, it was contended that Mr. Seaward's results were open to objection.

Mr. Pole then proceeded to notice the objections urged against the fundamental laws of friction which he had stated, and to give authorities for them. The first of these had not been questioned since the days of Vince, by whom it was proved; it might therefore be considered as established. With regard to the second and third, it must be noticed that they depended, in some measure, upon each other, for it could be proved that if the third was true, the second must be true also. The principal experiments which had been made upon the friction of solids, were those by Amontons, in 1699; Coulomb, in 1779; Vince, in 1784; Wood, in 1818; Rennie, in 1828; and Morin, in 1831, 32, and 33. Amontons was the first who devoted any considerable attention to the subject, and he found that friction was not augmented by an increase of surface, but only by an increase of pressure.[5] Coulomb's researches were more elaborate, the experiments were on a large scale, and were submitted to a great variety of trials; they fully proved that the friction was proportional to the pressure, and that the extent of surface did not affect it.[6] These results were further confirmed by the experiments of De la Hire, Ximenes, Boistard, Rondelet, and others. Mr. George Rennie's experiments were very valuable, as having been conducted on a large scale, and with much care; they were also of a comparatively recent date. The results were conclusive on the point in question, for he found that when the surfaces were to each other as 6·22 : 1, the friction remained the same,[7] and one of the general conclusions he deduced was, "that the amount of friction was as the pressure directly, without regard to surface, time, or velocity."[8] The last and most extensive series of experiments were those by M. Morin; they were conducted at Metz, by order of the French government, and ex-

tended over a period of three years (1831, 1832, and 1833), no expense or trouble having been spared to render them conclusive and satisfactory.[9] The results were given by Professor Moseley, in his new work on the mechanical principles of engineering.[10] They proved that "the friction of any two surfaces was directly proportioned to the force with which they were pressed perpendicularly together," and that "the amount of friction was, in every case, wholly independent of the extent of the surfaces of contact."[11] The before mentioned experiments all agreed, that the friction was proportional to the pressure, and was independent of the extent of surface. In opposition, however, to these, stood the experiments of Professor Vince, of Cambridge,[12] which led him to the conclusion that the friction increased in a less ratio than the pressure, and that it was not altogether independent of the area of surface. These experiments were probably conducted with care and accuracy; but it was also probable that equal precision had been used in those which proved the contrary; and if this was allowed, the majority of coinciding experiments might, as in all other cases, be safely received in preference to one dissentient. But if the particulars of Professor Vince's experiments were examined, many circumstances appeared which would render them less worthy of regard than others. It was not shown that he experimented upon metals, but that he used pieces of wood, either bare or covered with paper, and the experiments were on a small scale, the moving bodies being at the utmost a few ounces weight; while Coulomb, Rennie, and Morin, had extended their trials to all kinds of materials, and had used considerable weights. Professor Vince himself, although satisfied with the method of conducting his experiments, did not seem equally so with their results, as regarded the influence of surface and pressure, for he had remarked, "that no general rule could be established to determine it, even for the same body."

Quotations were then given from Gregory, Brewster, and others, corroborating this view of the inconclusive and unsatisfactory nature of Vince's experiments. The law of the influence of pressure and surface upon friction, was occasionally modified by accidental circumstances, two of which might be noticed, as they had been expressly treated of by Rennie and Morin.

1. It was only applicable within the limit of pressure which would not injure and abrade the surfaces; for when heating and undue attrition commenced, it was natural that the law would not hold good. Well-constructed machinery, however, was never supposed to pass this limit, and therefore this cause of irregularity might be rejected in calculation.

2. Another modification was produced by the application of unguents; this was treated of by Mr. Wood,[13] whose experiments showed that when unguents were introduced, there was a certain area of bearing surface, proportioned to the weight, which was peculiarly favourable as regarded the loss by friction, but that when this area was preserved, the friction was in strict ratio to the pressure.

It could not, however, have been Mr. Wood's intention, from these results, to impugn the applicability of the established general laws to the purposes of calculation, but only to show the existence of modifying circumstances under certain conditions; for the formula he had given[14] assumed the friction to be as the weight, and had no element in it expressing the area.

Mr. Rennie and M. Morin had also examined the influence of the unguents, and had found that their introduction did not materially alter the general laws of friction, but only affected the value of the co-efficient or multiplier to be used in ascertaining its numerical amount.

Having thus brought before the meeting the result of the principal experiments on friction, Mr. Pole concluded by adducing the testimony of writers on mechanics, who guided by these results, had promulgated the laws deduced from them. He gave quotations from the following authors in corroboration of his views, *viz.*—Emerson,[15] Playfair,[16] Tredgold,[17] Barlow,[18] Lardner,[19] Farey,[20] De Pambour,[21] Poisson,[22] Pratt,[23] Whewell,[24] and Moseley.[25] With the last mentioned author Mr. Pole had taken an opportunity of conversing upon the points in question, and the principles adopted in the paper had received the Professor's full approbation as corresponding with those made use of in his own treatises.

Mr. Vignoles thought that great praise was due to Mr. Pole, for the research and mathematical reading exhibited in treating the question of comparative friction. In the former remarks he had made, it was not his intention to impugn the accuracy of the abstract proposition, "that friction was independent of the area of bearing surface," any further than to qualify it in its practical application, with the proviso, "that proper proportions were maintained between the area and the pressure, according to the description of mechanism, subjected to friction." He therefore desired to consider the question, as to how far in practice one kind of engine varied from the other in the general amount of friction, and to examine how far the areas of the bearing surfaces, were in proportion to the insistent weight, caused either by the strain of any angle or by the direct weight on any of the journals of the moving parts; this inquiry should precede the abstract mathematical investigation. The friction of different substances would not follow the mathematical rule, unless the due proportion between area and pressure was ascertained and observed; these proportions would be very different in heavy machinery, such as marine steam-engines, and the axles of railway carriages. With these qualifications he agreed with the general propositions laid down by Mr. Pole.

Mr. Murray agreed with Professor Vignoles in thinking that the extent of surface in machines materially affected in practice the amount of the friction. He did not mean to advocate the correctness of Professor Vince's experiments, but he would draw attention to the results quoted by Dr. Gregory,[26] in which the difference of Vince's experiments and those of other writers on the subject, was attributed to their not taking into account the cohesion of the bodies experimented upon. Their experiments were made with inclined planes, which were raised until the bodies began to move, and the amount of friction was then deduced from the angle of inclination that had been given to the plane: from this mode it was contended that no definite laws could be laid down. Mr. Murray acknowledged that on dry surfaces, within certain limits, the amount of friction was not influenced by the extent of surface; but he contended that in practice, as different kinds of unguents were used, the cohesion arising from the impurity and clamminess of these lubricating substances, must be considered and allowed for.

Major-General Pasley said that when he was quartered at Malta, he tried some experiments on friction, by having a slab of Maltese stone, which resembled the oolite of Bath, rubbed smooth and placed horizontally; other pieces of smooth-faced stone of the same quality, but of different areas, were then attached to a cord which was weighted and passed over a pulley; the weights which were just sufficient to give motion to the several pieces of stone, were then noted, and it was found that the area of the surface was not important, the friction being directly in proportion to the insistent weight of the stone. He could therefore corroborate Mr. Pole's propositions.

Mr. Farey considered that Mr. Pole had treated the subject of friction so well, and had selected his authorities in such a manner as to establish his position incontrovertibly; he would therefore only remark, that in collating the friction experiments for his work from Dr. Gregory and others, he had in a measure rejected those of Vince, as being on too small a scale, and not of sufficient importance to rely upon as authority. It must be admitted, that viewing the question practically, there were circumstances which would influence the proposition. If the surface of a journal was so small as to drive out the unguent, or to cut into the lower bearing, the friction would be unduly increased, and the theoretical position would no longer hold good. The use of unguents would not interfere with the general proposition, although in practice, any substance used for lubrication, which, when cold, solidified and became adhesive, might, for a time, produce an increase of friction; this of course would be avoided, but it would not bear upon the general question.

Mr. Rennie corroborated the position assumed by Mr. Pole, "that friction was independent of the extent of the rubbing surface;" his experiments, which had been tried on a large scale, and with various substances, gave uniformly this result, within the limits of abrasion; when that commenced, the bearings heated and there was an end of the theoretical position. The texture also, of the rubbing surfaces altered the condition; for instance, any light body covered with cloth opposed a considerable resistance by the friction of the raised nap; but if the body was weighted, it again came within the limits of the law, because it more nearly resembled hard substances, which alone were considered in theory. Hard and soft woods varied, of course, in the same manner. The friction upon each other of metals of different degree of hardness, caused in practice, some little variation, but it was so slight, that the rule quoted, might be safely received as correct.

Mr. Davison stated that he some time ago made several practical experiments with an Indicator, constructed by Messrs. Maudslays and Field, for the purpose of ascertaining the power required to drive various kinds of machinery, in Messrs. Truman, Hanbury, Buxton, and Co's Brewery.

1st. He found, that an engine which indicated 50 horses power when fully loaded, showed, after the load and the whole of the machinery were thrown off, 5 horses, or one-tenth of the whole power.

2nd. 190 feet of horizontal, and 180 feet of upright shafting, with 34 bearings, whose superficial area was 3300 square inches, together with 11 pair of spur and bevel wheels, varying from 2 feet to 9 feet in diameter, required a power equal to 7·65 horses.

3rd. A set of three-throw pumps, 6 inches in diameter, pumping 120 barrels per hour, to a height of 165 feet, = 4·7 horses.

By the usual mode of calculation, (viz., 33,000 lbs. lifted one foot high per minute,) it would appear that there was, in this case, friction to the extent of 13 per cent.

4th. A similar set of three-throw pumps, 6 inches in diameter, pumping 160 barrels per hour, to a height of 140 feet, = 6·2 horses.

By the same mode of calculation as before, there was here, friction to the amount of 15 per cent.

[26] Gregory's Mechanics, vol. ii. p. 25.

5th. A set of three-throw pumps, 5 inches in diameter, raising 80 barrels per hour, to a height of 54 feet, = 1 horse.

By calculation, as before, the friction amounted to 12½ per cent.

6th. A set of three-throw "starting" pumps, pumping 250 barrels of beer per hour, to a height of 48 feet, = 4·87 horses.

By calculation as before, the friction amounted to 15½ per cent.

7th. Two pair of iron rollers and an elevator, grinding and raising 40 quarters of malt per hour, = 8·5 horses.

8th. An ale-mashing machine, made by "Haigh," of Dublin; mashing at the time, 100 quarters of malt, = 5·68 horses.

9th. Two porter-mashing machines, made by "Moreland," mashing at the time, 250 quarters of malt, = 10·8 horses.

10th. 95 feet of horizontal "Archimedes screw," 15 inches diameter, and an elevator, conveying 40 quarters of malt per hour, to a height of 65 feet, = 3·13 horses.

Mr. Davison promised to continue these experiments, and to communicate the results to the Institution.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

March 7.—J. Shaw, Esq., in the Chair.

A paper "*On the contemplated Restoration of the beautiful Chapter House at Salisbury Cathedral,*" was read, by Mr. T. H. Wyatt, Architect to the Salisbury Diocesan Church Building Association, which is printed in full in the present number.

Mr. Ferrey read a paper "*On an old staircase at Tamworth Church which has fallen into decay.*" It is a sort of double corkscrew stair, winding in such a manner over each other, that two persons may go up and down without meeting, although both are circulating in the same well-hole. Mr. Ferrey offered some remarks as to its probable purpose. It is said to be a solitary instance of this exact kind of stair in England, but we remember to have seen one at Cologne.

April 3.—His Royal Highness Prince Albert, the Patron of the Institute, presided at a general meeting of the members, and presented the medals awarded during the session, for essays and drawings. His Royal Highness arrived punctually at the time appointed, attended by Colonel Bouverie; he was received by the Vice-Presidents, and the Honorary Secretaries, and conducted to the Library, where the other members of the Council being assembled, were severally presented. The Prince then presided at a Council, at which some ordinary routine business was transacted; and, subsequently, having inspected the various antiquities, casts and models in the collection, proceeded to the large room, where his Royal Highness took the chair, and the business of the day was commenced. The minutes having been read, and some donations announced, Mr. Donaldson, Foreign Secretary, read letters from Italian and French correspondents, at Milan, Coblentz, and Paris.

Mr. Fowler, Honorary Secretary, read Bacon's Description of a Princely Palace; and Mr. A. Johnson was presented to the Prince as the author of the best design founded on that description, and received the Soane medal. In like manner his Royal Highness presented to Mr. E. Chamberlain, of Leicester, the medal of the Institute, for his essay on the subject proposed, "*Are Synchronism and Uniformity of Style essential to beauty and propriety in Architecture;*" and to Mr. J. W. Papworth, the medal of merit, for an essay on the same subject.

Mr. Bailey announced the subjects for essays and drawings, for which the Council propose to offer the medals for the ensuing year, and then read a communication from Mr. C. Parker, "*On the modes usually adopted in forming Foundations in the city of Venice,*' the soil of which city is of a nature to require the greatest care, and yet where failure is seldom if ever seen.

At the conclusion of the proceedings Mr. Barry addressed the Prince in the name of the Institute, and expressed, in a few words, the grateful sense entertained by the members, of the honour conferred on the body by the gracious manner in which his Royal Highness had acceded to their wishes in presiding on the occasion: to which his Royal Highness very graciously replied, that he had felt much pleasure in taking part in the proceedings of the day.

THE NEW HOUSES OF PARLIAMENT.

The Commissioners on the fine arts, of which Prince Albert is the head, having called upon Mr. Barry, as architect, to furnish them with a report as to his views relating to the "internal decorations, additions to building, and local improvements," that gentleman transmitted his report to his Royal Highness and the Commission last month. Judging the subject as likely to interest our readers, especially as many of the suggestions offered by Mr. Barry will undoubtedly be carried out, we place the following particulars of the proposed decorations, &c. before our readers, for which we are indebted to the *Morning Herald.*

"As presiding over her Majesty's commissioners for encouraging the fine arts in connection with the rebuilding of the new Houses of Parliament, I venture to address your Royal Highness, and, in compliance with the instructions of the commission, to offer the following suggestions relative to the internal finishings and decorations of the new Houses of Parliament, the completion of the exterior and local improvements, which are, in my opinion, necessary to give full effect to the new building; and by way of illustration of the remarks I have to make on these subjects, I beg to transmit the accompanying plan of the principal floor of the new building, a general plan of part of Westminster, in which the new building is shown in connection with various improvements proposed to be made in its locality, and two drawings relating to Westminster-bridge.

THE DECORATIONS.

"With reference to the interior of the new Houses of Parliament generally, I would suggest that the walls of the several halls, galleries, and corridors of approach, as well as the various public apartments throughout the building, should be decorated with paintings having reference to events in the history of the country; and that those paintings should be placed in compartments formed by such a suitable arrangement of the architectural designs of the interior as will best promote their effective union with the arts of sculpture and architecture. With this view, I should consider it to be of the utmost importance that the paintings should be wholly free from gloss on the surface, that they may be perfectly seen and fully understood from all points of view. That all other portions of the plain surfaces of the walls should be covered with suitable architectonic decoration, or diapered enrichment in colour, occasionally enlivened with gold, and blended with armorial bearings, badges, cognisances, and other heraldic insignia, emblazoned in their proper colours. That such of the halls as are groined should have their vaults decorated in a similar manner, with the addition occasionally of subjects or works of art so interwoven with the diapered ground as not to disturb the harmony or the effect of the architectural composition. That such of the ceilings as are flat should be formed into compartments by moulded ribs, enriched with carved heraldic and Tudor decorations. That those ceilings should be relieved by positive colour and gilding, and occasionally by gold grounds with diaper enrichments, legends, and heraldic devices in colour. That the screens, pillars, corbels, niches, dressings of the windows, and other architectural decorations, should be painted to harmonise with the paintings and diapered decorations of the walls generally, and be occasionally relieved with positive colour and gilding. That the door-jambs and fire-places should be constructed of British marbles of suitable quality and colour, highly polished, and occasionally relieved by colour and gilding in their mouldings and sculptural enrichments.

"That the floors of the several halls, galleries, and corridors should be formed of encaustic tiles, bearing heraldic decorations and other enrichments in colours, laid in margins and compartments, in combination with polished British marbles; and that the same description of marbles should also be employed for the steps of the several staircases.

"That the walls, to the height of from eight to ten feet, should be lined with oak framing, containing shields with armorial bearings emblazoned in their proper colours, and an oak seat should in all cases be placed against such framing. That the windows of the several halls, galleries, and corridors should be glazed doubly, for the purpose of tempering the light and preventing the direct rays of the sun from interfering with the effect of the internal decorations generally. For this purpose the outer glazing is proposed to be of ground glass, in single plates, and the inner glazing of an ornamental design in metal, filled with stained glass, bearing arms and other heraldic insignia in their proper colours; but so arranged as that the ground, which I should recommend to be of a warm yellowish tint, covered with a running foliage or diaper, and occasionally relieved by legends in black letter, should predominate, in order that so much light only may be excluded as may be thought desirable to do away with either a garish or cold effect upon the paintings and decorations generally. Practically, I consider that the double glazing will be of essential service in carrying out the system of warming and ventilating proposed to be adopted in the building generally; which system renders it unnecessary that the windows in those portions of the building above referred to should be made to open, so that all prejudicial effects upon the paintings and other decorations, which might be caused by the dampness and impurity of the atmosphere, and much practical inconvenience, and probably unsightliness in the means that would be necessary to adopt for opening and shutting casements would be avoided.

"That, in order to promote the art of sculpture, and its effective union with painting and architecture, I would propose that in the halls, galleries, and corridors, statues might be employed for the purpose of dividing the paintings on the walls. By this arrangement a rich effect of perspective, and a due subordination of the several arts to each other would be obtained. The statues suggested should, in my opinion, be of marble, of the colour of polished alabaster, and be raised upon lofty and suitable pedestals, placed close to the wall, in niches, surmounted by enriched canopies; but the niches should be shallow, so that the statues may be as well seen laterally as in front.

"The architectural decorations of these niches might be painted of such colours as will give the best effect to the adjoining paintings, being relieved in parts by positive colour and gilding; and the backs of them might be painted in dark colours, such as chocolate, crimson, or blue, or they might be of gold, for the purpose of giving effect to the statues.

"Having thus described the views I entertain as to the character of the decorations of the interior generally, I now proceed to notice in detail the special decorations and arrangements which I would propose for the several halls, galleries, and principal apartments.

WESTMINSTER HALL.

"I would propose that Westminster Hall, which is 239 feet long, 68 feet wide, and 90 feet high, should be made the depository, as in former times, for all trophies obtained in wars with foreign nations. These trophies might be so arranged above the paintings on the walls and in the roof as to have a very striking and interesting effect.

"I would further suggest that pedestals, 20 in number, answering to the position of the principal ribs of the roof, should be placed so as to form a central avenue, 30 feet wide, from the north entrance door to St. Stephen's porch, for statues of the most celebrated British statesmen, whose public services have been commemorated by monuments erected at the public expense, as well as for present and future statesmen whose services may be considered by Parliament to merit a similar tribute to their memories.

"The statues (26 in number) which have already been proposed to be placed against the walls, between the pictures, I would suggest should be those of naval and military commanders.

"The subjects of the paintings on the walls, 28 in number, 16 feet in length and 10 feet in height, might relate to the most splendid warlike achievements of English history, both by sea and by land, which, as well as the statues that are proposed to divide them, might be arranged chronologically.

"To give due effect to those suggested decorations, it is proposed that the light should be considerably increased by an enlargement of the dormer windows in the roof, by which also that extraordinary and beautiful piece of decorative carpentry of the 14th century may be seen to much greater advantage than has ever yet been the case.

"This noble hall, certainly the most splendid in its style in the world, thus decorated by the union of painting, sculpture, and architecture, and aided by the arts of decoration as suggested, it is presumed would present a most striking appearance, and be an object of great national interest.

ST. STEPHEN'S HALL.

"I would suggest that this hall, which will be 90 feet long, 30 feet wide and 50 feet high, and have a stone-groined ceiling, should be appropriated to the reception of paintings, commemorative of great domestic events in British history, and statues of celebrated statesmen in past, present, and future times. The paintings may be 10 in number, 15 feet long and 10 feet high, and 12 statues would be required as a frame to them. In the upper part of the hall, 30 niches will be provided for statues of eminent men of the naval, military, and civil services of the country.

THE CENTRAL HALL.

"This hall will be an octagon of 60 feet in diameter, and 50 feet high, covered with a groined ceiling in stone. As each side will be wholly occupied with windows, and arched openings of access, paintings cannot form any part of its decoration. It may, however, with good effect, be extensively decorated with sculpture. In the centre of the pavement might be placed a statue of her present Most Gracious Majesty, upon a rich pedestal of British marble, highly polished, and relieved in parts by gold and colour. The niches in the walls and screens might be filled with statues of her Majesty's ancestors, in chronological order, even up to the period of the Heptarchy. In front of the eight clustered pillars in the angles of the hall, might be placed, with good effect, sedent statues of some of the great lawgivers of antiquity.

THE VICTORIA GALLERY.

"This gallery will be 130 feet long, 45 feet wide, and 50 feet high, with a flat ceiling, and will admit of both paintings and sculpture. The subjects of the paintings on the walls, 16 in number, which may be 12 feet long and 10 feet high, might relate to some of the most remarkable royal pageants of British history or other appropriate subjects. Statues of her present Most Gracious Majesty might fill the central niches at the ends of the hall, and the other niches, as well as the pedestals between the paintings, might be occupied by statues of her Majesty's ancestors. These statues might, with good effect, be of bronze, either partially or wholly gilt.

CORRIDORS OF ACCESS THROUGHOUT THE BUILDING.

"The principal corridors of access to the various apartments of the building will be 12 feet wide, their ceilings will be flat, and they will be generally lighted from windows near the ceiling. The walls may be decorated with portraits as well as paintings, illustrative of some of the most remarkable events in the history of the country, or in the lives of its most eminent personages. For this purpose about 2,600 feet in length of wall, by a height of about seven feet, may be appropriated on the principal floor: 900 feet in length, by a height of about seven feet on the one-pair floor; and about 400 feet, by the same height, on the two-pair floor. These paintings may be divided into subjects at pleasure, by margins or borders of architectonic decoration in accordance with the style of the building.

THE HOUSE OF LORDS.

"This house will be 93 feet long, 45 feet wide, and 50 feet high, will have a flat ceiling in panels. As the fittings for the accommodation required for the business of the house, together with the windows, which are necessary for duly lighting it, leave little space of plain wall, paintings cannot, with good effect, form any part of its decoration. Niches, however, will be provided, which might be filled with statues of royal personages. The architectural details of the ceiling may be enriched and relieved with gold and colour, and the windows filled with stained glass as before described. The whole of the fittings are proposed to be of oak, with appropriate carvings. The throne will be highly enriched and relieved by colour and gilding, and the back lined with cloth of gold, containing the royal arms emblazoned in colours.

THE HOUSE OF COMMONS.

"This house will be 83 feet long, 46 feet wide, and 50 feet high, and will have a flat ceiling. It is proposed to be finished in the same style as the House of Lords, but with less enrichment, and less of colour and gold in its decorations. The nature of its designs, and the extent of its fittings for the accommodations required, will not admit of either painting or sculpture.

THE QUEEN'S ROBING-ROOM.

"This room will be 38 feet long, 35 feet wide, and 20 feet high, and have a flat ceiling in panels, richly moulded and carved, and relieved with gold and colour. The ground of the panels of the ceiling is proposed to be of gold, covered with a diaper enrichment, and blended with legends, genealogical devices, badges, cognisances, and other heraldic insignia, and in colour.

"The wall-fittings of the room are proposed to be of oak, richly carved and moulded, and enriched with heraldic and other decorations in positive colour, relieved with gold. Compartments will be formed in the wall-framing, which might be filled with paintings referring to events in British history in which the Sovereign has personally taken a conspicuous part, or with other appropriate subjects.

THE ANTI-ROOM, OR GUARD-ROOM.

"This room which adjoins the Queen's robing-room, will be 38 feet by 38 feet, and 20 feet high. The ceiling will be of oak, with characteristic decorations. Oak framing, eight feet high, with heraldic decorations, and a seat at the foot of it, will line the room. The walls are proposed to be covered with representations of battle-scenes, and pageants of English history, in which an opportunity would be afforded of displaying the warlike costumes of its several periods.

THE CONFERENCE HALL.

"This hall, which is in the centre of the front towards the river, will be 54 feet long, 28 feet wide, and 20 feet high, and will have a flat ceiling. The walls are proposed to be lined with oak framing to the height of about 6 feet, above which they might be covered with paintings representing celebrated state trials, and extraordinary sittings of Parliament, conferences, &c.

AS TO THE APARTMENTS APPROPRIATED TO THE PRIVATE AND PUBLIC USES OF EACH HOUSE.

"These rooms consist of libraries, refreshment rooms, robing rooms, state officers' rooms, and committee rooms.

"Nine rooms are appropriated to libraries, six of which are fifty feet long, and 28 feet wide; two are 33 feet long, and 28 feet wide; and one is 32 feet long, and 23 feet wide. The refreshment rooms are four in number, of which one is 60 feet long and 18 feet wide; two are 28 feet long and 18 feet wide; and one is 31 feet long and 18 feet wide. The robing rooms for the archbishops and bishops are three in number, of the respective sizes of 30 feet by 20 feet, 20 feet square and 16 feet square. The robing and other rooms for state officers are seventeen in number, averaging in size about 24 feet by 18 feet. The committee rooms are thirty-five in number. On the principal floor, five of them will be 37 feet long by 28 feet wide; two 35 feet by 26 feet; and one 32 feet by 23 feet. On the one-pair floor, two will be 42 feet long and 33 feet wide: one 54 feet by 28 feet; four 36 feet by 28 feet; ten 34 feet by 28 feet; and two 34 feet by 22 feet; and on the two-pair floor the number will be eight, averaging in size 28 feet by 20 feet. The whole of these rooms are about 20 feet in height, with the exception of those on the two-pair floor, which will be about 14 feet high, and will be lighted by windows of the usual height from the floor.

"The ceilings will be flat and formed into panels by moulded and carved ribs, relieved by characteristic and suitable carvings.

"The floors are to be of oak, with borders and inlays.

"The fire places and door jambs are proposed to be of British marbles, highly polished. The doors, frontispieces, linings of walls, and fittings, will also be of oak. In some of the rooms it is proposed that the wall framing should be carried to the height of six or eight feet, in others that it should be of the full height of the room, and with panels for paintings, portraits, &c.

"The plain surfaces of the walls might be covered with paintings of historical events, and the panels in the wainscoting might contain portraits of celebrated personages in British history.

"The architectural details, both in stone and plaster, might be painted in positive colours, occasionally relieved with gilding; and the armorial bearings, badges, and other heraldic insignia which will enrich the wood-framing, might also be relieved with gold and colour.

THE SPEAKER'S RESIDENCE.

"This residence, being designed for state purposes, might also be adorned with paintings. The style of its finishings, fittings and decorations will be in accordance with the best examples of the Tudor period.

"Its principal rooms for the purposes of state are as follows:—A reception-room, 34 feet by 23 feet; a library, 34 feet by 23 feet; a dining-room, 45 feet by 24 feet; a drawing-room, 38 feet by 22 feet; and a corridor of communication, 8 feet wide, surrounding an internal court.

"With respect to any further encouragement of the fine arts in the exterior of the building, I am not aware of any opportunities that offer, as arrangements have already been made for all the architectonic or conventional sculpture that will be required to adorn the several elevations. Equestrian statues of sovereigns in bronze might, however, be placed with considerable effect in the proposed quadrangle of New Palace-yard, the Speaker's quadrangle, and the royal court.

"I have now described, in general terms the whole of those portions of the building that might, I think, with propriety and effect be adorned with works of art, and the arts of decoration; but in making the several suggestions which have occurred to me, I should wish it to be understood that I have merely stated my own views on the subject, as far as I have hitherto been able to consider it in its general bearings, and with a view to show how the objects for which the commission has been established may, if desired, be carried out in the decorations of the new building to their greatest extent. I should not however, wish to be strictly confined in all cases to the adoption of even my own suggestions, as upon a more mature consideration of the subject in detail hereafter, when the shell of the building is completed, I may be induced to vary and modify some of the views which I entertain at present, and which, I fear, I have but imperfectly communicated in this paper.

AS TO THE COMPLETION OF THE EXTERIOR.

"It has ever been considered by me a great defect in my design for the new Houses of Parliament that it does not comprise a front of sufficient length towards the Abbey, particularly as the building will be better and more generally seen on that side than any other. This was impossible, owing to the broken outline of the site with which I had to deal. I propose, therefore, that an addition should be made to the building for the purpose of enclosing new Palace-yard, and thus of obtaining the desired front. This addition would be in accordance with the plan of the ancient palace of Westminster, in which the hall was formerly placed in a quadrangle, where, in consequence of its low level, it must have been seen and approached, as it would be, under such circumstances, to the best advantage. The proposed addition would, in my opinion, be of considerable importance as regards the increased accommodation and convenience that it would afford in addition to what is already provided for in the new building as hitherto proposed.

"It has long been a subject of serious complaint and reproach that the present law courts are most inconveniently restricted in their arrangements and accommodation. If it should be determined to retain the courts at Westminster, the proposed addition would admit of the means of removing this cause of complaint; it would also afford accommodation for places of refreshment for the public, for which no provision has been made in the new building, also for royal commissions and other occasional purposes required by Government, and now hired most inconveniently, in various parts of the town, at a considerable amount of rental: or for such of the Government offices as may, without inconvenience, be detached from the rest, such as, for instance, the office of woods, or for a record office, and chambers or residences for public officers. It will also afford the opportunity of making an imposing principal entrance to the entire edifice at the angle of Bridge-street and St. Margaret-street—a feature which is at present required, and which would add considerably, not only to the effect of the building, but also to its security in times of public commotion.

"Of the several local improvements suggested, none, in my opinion, is of greater or more pressing importance than that which I have to suggest in respect to Westminster-bridge. The anomaly of the size, outline, and character of that bridge, considered, as it ever must be from its proximity, as an adjunct to the new Houses of Parliament, must have forcibly struck every one who has passed over or under it since the new building has risen into importance; and the steep and dangerous declivities of the roadway, as well as its want of width for the traffic that passes over it, have constantly been a subject of public complaint.

"In order, therefore, to remove these serious objections, I propose that the superstructure of the bridge should be rebuilt upon the old foundations, which are now in course of being repaired and extended under the able superintendence of Messrs. Walker and Burgess. As it is, in my opinion, of the utmost importance, both as regards the effect of the new Houses of Parliament when viewed from the bridge, and the convenience of the public in passing over it, that the roadway should be made on the *lowest possible level*, I would recommend that the form of the arches of the new bridge should be pointed, by which great facility would be afforded for the accomplishing that very important object, namely, by materially reducing the thickness of the crown of the arches within what is considered necessary for arches of the circular form. I am induced also to recommend this form of arch on account of another very important practical advantage which it offers, namely, the elevation of its springing above the level of high water, by which the water-way through the bridge will be the same at all times of tide; whereas at present the spandrels of the arches offer an impediment to the water-way at high water nearly equal to 1-20th of its sectional area, occasioning rapid currents, with a considerable fall, and sometimes much danger to craft in passing through the bridge, under the influence of high winds. I consider it also of the greatest importance in an artistic point of view, not only that the bridge should be materially lowered, but that it should be made to accord with the new Houses of Parliament, in order that both in composition as well as style the *ensemble* should be harmonious and effective. Upon a rough estimate which I have formed of the cost of the new superstructure, I am satisfied it could be erected for about £120,000 beyond the cost it will be necessary to incur to carry out Messrs. Walker and Burgess's design for widening the present bridge to the extent proposed."

Mr. Barry, in continuation observes, it is clearly to be understood he has no desire to interfere with the employment of the engineers who are now engaged in the repair and extension of the foundations, whom he strongly recommends should be left to complete it. He expresses a hope that the commissioners, if they should think fit, will at their earliest convenience make a formal and urgent communication to the Government in accordance with the above views he has laid before them, as an early decision would be of great importance, in order that the works in hand may not be proceeded with farther than is necessary to carry out those views if they should be ultimately adopted.

The embankment on both sides of the river, from Vauxhall-bridge to London-bridge, he considers next in importance to the rebuilding of the superstructure of Westminster-bridge. He says:—

"As there would, doubtless, be serious objections to a public road upon the embankment on the north side of the river, I confine my observations to the southern side, where, if a road could be obtained, it would afford a succession of fine views of London, and the best situation for views of the principal front of the new houses of Parliament. Having maturely considered the subject, I think it would be practicable to obtain a public road of ample width upon arches, from the termini of the South-Eastern and Dover and the Brighton Railroads, at the foot of London-bridge to the terminus of the South-Western railway at Vauxhall.

"The road might be raised upon arches to a level that would coincide with the levels of the roadway of the several bridges which it would intersect, by which means the water-side frontages of the several wharfs need not be interfered with in any material degree; indeed, the extent of such frontages might, by the means of docks of convenient form and size, be very considerably increased, and the archways might, to a great extent, be appropriated, if desired, to warehouses and other purposes of trade. By extending the archways to a sufficient depth to the south of this road, a frontage for building might also be obtained, particularly opposite Privy Gardens and the new Houses of Parliament, where, if the houses were designed in masses, with reference to architectural effect, they would form an agreeable and striking view from the north side of the river, and effectually screen the present low and mean display of unpicturesque buildings on the Surrey side. The proposed houses, from being raised to a considerable elevation, would have a fine command of the river, and the principal public buildings of the metropolis, and having, in addition to these advantages, a southern aspect, would form very agreeable residences, such as would probably be eagerly sought for by the owners of adjoining wharfs, either for their own occupation, or that of their principal agents. Taking into consideration the private accommodation to the several wharfs, and the value of the new building frontage, the proposed work would probably yield a very considerable return for the capital expended upon it, and, when effected, would not only form one of the most striking improvements of an ornamental character of which the metropolis is susceptible, but would materially conduce to the convenience, the comfort, and the recreation of the public. It would also perhaps render unnecessary the line of road that has been projected from the termini of the railroads at the foot of London-bridge, through Southwark to the foot of Westminster-bridge, for the convenience of the west end of the town, as the distance to that part of London would be materially shortened by taking the proposed embankment road, and passing over Waterloo-bridge."

Of the local improvements immediately contiguous to the new Houses of Parliament and the approaches, Mr. Barry in continuation remarks:—

"Old Palace-yard is proposed to be considerably increased in size by the demolition of the houses which now occupy that site, as well as the houses on both sides of Abingdon-street, by which means a fine area for the convenience of state processions, and the carriages of peers and others attending the House of Lords, as well as a spacious landing-place adjoining the river, would be obtained. The Victoria Tower, as well as the south and west fronts of the building, would thus be displayed to the best advantage. The Chapter house would be laid open to public view, and if restored, would form a striking feature in conjunction with the Abbey; and a considerable extent of new building frontage that would be obtained by this alteration might be occupied by houses of importance, in a style of architecture in harmony with the Abbey and the new Houses of Parliament, by which a grand and imposing effect as a whole would be produced. As one means of improving the approaches I propose that the noble width of street at Whitehall should be extended southwards by the removal of the houses between Parliament-street and King-street, by which the Abbey would be wholly exposed to view as far as Whitehall Chapel. The houses on the north side of King-street should be removed for the purpose of substituting houses or public buildings—if required, of an improving style of architecture.

"Millbank Street is proposed to be widened and improved in order to make it a convenient and effective approach from Millbank Road to the Victoria Tower and Old Palace Yard. Tothill Street is also proposed to be widened and improved in order that it may be made an equally convenient and striking approach to the Abbey, the Houses of Parliament and Whitehall from the west-end of the town. St. Margaret's Church, if suffered to remain in its present position should be improved in its external decoration, in order that it may not disgrace, as it now does, the noble pile of the Abbey, which rises above it."

Mr. Barry concludes the enumeration of all the principal improvements he judges to prove most effective to the building on which he is engaged, by the hope, although some might be considered impracticable, that at no distant period the rebuilding of the superstructure, the embankments of the river, the enclosure of New Palace Yard, and the enlargement of Old Palace Yard, may be accomplished as "improvements of the utmost importance, whether as regards the beauty of the metropolis, the effect of the new Houses of Parliament, or the convenience, as well as the enjoyment of the public."

THE IPSWICH COMPETITION AND IPSWICH CUSTOM-HOUSE.

Sir—Notwithstanding that so very much has been said on the subject of competition generally, and also in regard to particular cases of it, never has a more striking proof of the manner in which such matters are *managed*, been brought forward, than that furnished by the competition now in progress for a new Custom-House at Ipswich. This I think will be admitted by every one on reading the following statement and correspondence, for which I solicit insertion in your *Journal*, in order that the profession and the public may be acquainted with the whole affair, and clearly perceive how monstrously absurd are the so-called "Instructions to Architects," sometimes put forth on such occasions. No doubt this Ipswich affair is a very trumpery one in every meaning of the word—most remarkably so; and on that very account does it call for strong animadversion and exposure; since it is owing to so many things of the kind being quietly passed over, as too insignificant for notice, or because it is worth no one's while in particular to make any "fuss" about them, that they at length become an established system. Silence on the part of the profession looks like acquiescence, and local "committees," relieved from the wholesome fear of committing themselves, perfectly irresponsible to public opinion, and at liberty to act just as they please, no matter how capriciously, how arbitrarily, or how absurdly. Bodies of that kind have, like private individuals, most unquestionably the right of pleasing themselves—that is, if they can, and also that of serving their own particular views and their own particular friends; but then it should be done in a different manner: for when they invite to competition by *public advertisement*, they become pledged to perfect fair dealing and impartiality, and bound to act with something like discretion. At all events, it may be supposed that they themselves have a tolerably distinct notion of what it is they do want, and ought, accordingly to express it as distinctly as they can: otherwise, the vagueness of their "instructions," either betrays their own incapacity, their inability to explain themselves in the first instance, and therefore, it may be inferred, their incompetence to judge afterwards on the designs admitted to them, or it very naturally excites a suspicion that all is not quite so fair and straightforward as it professes to be, but that the "instructions" have been conveniently mystified, in order not to enlighten people too much on the subject. Obscurity, we are told, is one source of the sublime: and if so, the committees who preside over competitions must be some of the sublimest people in the world.

One motive for my thus bringing forward this Ipswich affair, is the hope that the attention of the Institute of British Architects will now be called to it. It certainly is what it ought to take up; but although I belong to that body myself, I must own that it has hitherto shown itself by far too supine in all such matters: it is sadly deficient in that heartiness and zeal which, only exerted, would correct many abuses, and would no less directly than essentially benefit both the act and the profession. It ought not to leave to individuals in the latter, the onerous and not particularly gracious task of trying to effect what it is beyond the power of individual zeal and energy, however well directed to accomplish. The Institute, it may be presumed, possesses a certain degree of authority with public opinion: if so, let it exert that authority to some purpose, and beneficially. Let it convince the public that it is something more than a mere name, and that its influence extends beyond the walls of its own council-room. Unfortunately, however, those who have most weight and influence there, are least of all interested in bringing forward or promoting measures having for their object the interests of architecture and of the profession generally. That such should be the case is, perhaps, natural enough: why should those who are not at all personally affected by them, give themselves any concern about grievances and abuses which they do not feel, heavily as they may press upon and depress those who have to contend with them? The tranquility with which they view—for hardly can they be ignorant of them, may look like philosophy—like Mahommedan assignment to unavoidable evils; yet though their indifference may be very justifiable, all very prudent and proper, it certainly says nothing for their zeal, their generosity, or their public spirit; nor does it at all tend to raise the character of the Institute as a body in public estimation. *Tout au contraire*, it exposes it to animadversions all the more severe, because well merited. Perhaps I am now expressing myself rather strongly, and may besides be thought to spin out these remarks too largely, for I began them merely by way of preface to what follows, and to what I will now let follow at once without any further comment. "———"

"Instructions to Architects desirous of submitting designs for the proposed New Custom House, Ipswich, Suffolk.

"*To Architects.*

"The Corporation of Ipswich, propose to erect a public building upon the common quay, in that town, as a Custom-house and Excise-office; to comprise also, suitable offices for the accountant and collector of the dock commissioners, and other public business of the town connected with the mercantile and shipping interests; accommodation will also be required for the lessees or occupiers of the common quay wharf, which is the principal landing place for goods in the town, and any spare rooms may be adapted for private offices or a bonding warehouse.

"Cost. The expenditure not to exceed £4000.

"Premiums.—Twenty guineas will be given for the first selected plan, and ten guineas for the second. Such two plans to become the property of the corporation. The architect whose design is selected will most probably be employed to superintend the erection of the building, provided he can produce satisfactory testimonials as to his ability, &c.

"Site.—The site for the proposed building is an open space, measuring about 240 feet by 130 feet, with a water frontage.

"Motto.—The different drawings, &c., are to be distinguished by a motto, and the name and address of each architect to be sealed up in an envelope bearing the same motto as his design, which letter will be returned, unopened, to the unsuccessful competitors.

"The plans, &c., to be delivered at the town clerk's office, Ipswich, on or before the 1st of May next. The selection of the premium designs will be duly advertised in the local papers, after which, the remaining designs will be returned to their respective authors, on their writing for the same, stating the motto affixed to their various drawings, &c.

"S. A. Notcutt, Jun.,
"Town Clerk.

"Ipswich, March 1843."

11th April, 1843.

"Sir—I shall feel obliged by your favouring me with replies to the following queries relative to the competition for the new Custom-house, Ipswich.

"1st. Is it necessary for the competitor to see the ground previously to preparing his designs?

"2nd. What is the nature of the foundation? will it be requisite to use piling or concrete, or is the natural soil sufficiently solid to bear the ordinary foundations of a building of the size and nature required, without any extraordinary outlay for this part of the work?

"3rd. What accommodation will be required for the Custom-house and Excise-office, and what dimensions will be required for the rooms?

"4th. What is to be understood by 'suitable offices for the accountant and collector of the dock commissioners;' are there two or more rooms: and about what dimensions will they be required?

"5th. What accommodation will be required for the 'lessees or occupiers of the common quay wharf?'

"6th. What spare rooms are expected to be provided for offices and bonding warehouse, and what dimensions are they required to be?

"7th. Are all the rooms, warehouses, &c., contained in the first paragraph of the 'Instructions to architects,' to be included in the expenditure of £4000?

"8th. What distance is the wharf or water from the site of the proposed building

"9th. For the premiums, is it expected that the architects should furnish the *requisite number of drawings* in order that the corporation may form a just decision on the comparative merits of the various designs? Will it be necessary that they furnish the following? viz.

"Elevations of the four fronts; plans of the different stories, foundations and roofs; six or seven drawings; one longitudinal and two or three transverse sections; one or two perspective views, about 16 drawings; a specification of the work and a detailed estimate of the cost.

"10. What scale are the designs to be drawn to?

"11. Are the elevations to be coloured, tinted in the sepia or only to be drawn in outline?

"12. Are the perspective views to be taken from any fixed points? And are they to be coloured or tinted in sepia?

"13. What materials are to be used in the construction of the outside walls, and in whatever decoration the limited funds will allow?

"14. As the architect whose design is approved will '*most probably*' be employed to erect the building, may I ask if any designs have been laid before the corporation previously to the competition being proposed?

"15. Have the corporation an architect, or any one possessing a knowledge of architecture in their employ?

"16. Will any means be adopted to ascertain that the designs can be executed for the sums estimated?

"17. Will the corporation undertake to lay aside all designs which cannot be executed for the sums estimated?

"18. By whom are the designs to be examined and selected?

"19. Are the parties who examine and select the designs well acquainted with the principles of composition in architecture, as regards unity of style, fitness for the end in view, and harmony to which I may add the principles of construction, and the proper application of materials?

"20. Is the approved design to be in strict conformity to ancient precedent, or to be an original composition, possessing all the requisites of a work of fine art?

"21. In case the corporation should consider it necessary to call in the aid of a professional architect to assist them in the selection of the designs, will his report be delivered in writing, and will it be published or otherwise be made known to the competitors, in order that they may have an opportunity of reflecting any opinion therein contained?

"22. The time for sending the designs is exceedingly limited. It would be of considerable benefit to the corporation as well as the architects that a greater length of time was allowed for preparing the design; can the corporation grant such a request?

"23. Is it intended that the designs should be publicly exhibited previously to the decision of the corporation?

"24. Who are the members of the corporation that are to form the judges in the competition?

"I have to apologize for taking up so much of your time; but without the information herein required it will be impossible to furnish suitable designs for the proposed building.

"Your earliest reply will oblige,

"Yours, &c.,

"———."

"Ipswich, 13th April, 1843.

"Sir—I have your letter of yesterday. It is quite impossible for me to give the answers you require. £4000 is the total sum to be expended. The dock commissioners would only require two rooms, and these not large. The architect may choose the site of the building in the area, the dimensions of which are furnished in the paper already sent to you, except that a roadway of 30 feet from the water's edge must be left free of any building. There is no limit as to scale. The time for sending in drawings cannot be extended.

"I am, Sir,

"Your obedient humble servant,

"S. A. Nolcutt, Jun."

"14th April, 1843.

"Sir—I am exceedingly sorry to be so troublesome to you, but without the requisite data, it is impossible for any architect to prepare suitable designs for the Custom-house at Ipswich. If it is impossible for you to give me the information required, you may probably inform me to whom I am to apply. In the printed instructions to architects, there is so little information, that the whole accommodation required for the Custom-house is quite undefined; and whether the offices are for one or two clerks or more persons is not mentioned. I respectfully submit that the architect's answers to the queries I sent on the 11th instant should be given by the committee, who of course are fully aware of the accommodation they require. I shall feel obliged by an early reply.

"I am, &c.,

"———."

"Ipswich, 15th April, 1843

"Sir—I have to acknowledge the receipt of your letter of the 14th, and regret that I can afford little more information than has been already furnished to you in common with those gentlemen who have stated their determination to send in plans for the new Custom-house here.

"I can only say, generally, that the business of the port in both departments, custom and excise, is not likely to be very considerable, and the dock commissioners would not require more than a couple of moderate sized rooms. The limited expenditure must of course govern the extent of the accommodation.

"I am, Sir,

"Your obedient humble servant,

"S. A. Nolcutt, Jun."

"17th April.

"Sir—I should be wrong in expressing an opinion that the corporation of Ipswich were the only body who have published such vague instructions, when they require architects to prepare certain designs for the buildings they have it in contemplation to erect; was this the first instance of the kind, little could be said upon the subject, but as it is now the usual proceeding in most occasions of this nature, the profession, as a body, ought to complain; yet as a body, they do little, it therefore rests with individuals to do something.

"I would not for a moment suppose that the corporation have already decided who is to be the architect of the building, nor do I suppose that each member of that body has his particular friend to support, and therefore all the information he possesses is necessarily reserved for this friend, I say I cannot presume that this is the case, but the very great difficulty I have experienced in obtaining the *necessary* information so as to prepare the required designs, naturally creates a suspicion, especially as the numerous results of such proceedings confirm those suspicions. I presumed, when I wrote to you, that officially you had the power of answering all necessary questions, and that if you had not such power, at least you could direct me to some person who must have known what was required, better than a stranger, for the commercial business of the port. The dock commissioners, the accountant, the merchants, who are interested in the shipping, the occupiers of the common quay wharfs, the town clerk, and others interested or connected with the custom house, must individually have some idea of the accommodation; surely it would have been no great or difficult task to collect such information, in order that the corporation should get the *most suitable* design for their building—or if they do not know what they want, they can want nothing—this is a natural inference, and perhaps the least requiring an apology.

"I have to thank you for your letters, although you were unable to give me the information I required. It is my intention to publish in some periodical, the 'Instructions to Archiects,' my queries, and the correspondence I have had with you on this occasion, my only wish being to obtain, in business of this nature, all the information that the subject may require, and in which I have been so unsuccessful in this instance.

"The most extraordinary thing in this competition appears to me to be that the corporation are to select the most suitable design for their building, yet admit through their official organ, that they do not known what is required, at least I must come to this conclusion, as the information I required on the most important subjects could not be obtained.

"I am, &c.,

"———."

South-Eastern Railway.—(Folkstone.)—The works at this place are rapidly progressing under the contractors for the works, Messrs. Grissell and Peto, who it is expected will be able to place the line soon in the hands of Mr. Betts, the contractor for the permanent way, and there is now no doubt that the line will be in operation within seven miles of Dover before the end of July next, neither now is there any doubt expressed as to which will be the direct line to France.

REVIEWS.

MR. PUGIN'S NEW WORK.

An Apology for the Revival of Christian Architecture in England. By A. Welby Pugin, Architect, Professor of Ecclesiastical Antiquities at St. Marie's College, Oscott. Small 4to., Ten Plates. London, 1843. Weale.

To recommend this production to the notice of our readers, would be almost superfluous, since it is one which can hardly by any possibility *escape* notice, or fail to obtain greater attention than usually falls to the lot of architectural publications in general, or even of such as have more than ordinary merit to recommend them. Any thing proceeding from the author of the "Contrasts" and "True Principles," is certain of being taken up with curiosity, and with not the least degree of it by those in whom that feeling may be more or less mixed with apprehension, and who are therefore anxious to discover whether they themselves come in for any remarks from a pen that is not always exercised very gently. In one respect, Mr. Pugin is quite alone, not only from all other architectural writers, but from nearly all other writers whatever; he is no respecter of persons, but speaks as one having authority—openly, boldly, without any observance of the *suaviter in modo,* without attempting to conciliate any one, and without caring what individuals he may offend. Mawkish liberality and excessive "good nature" are not among Mr. Pugin's foibles; so far is he from excusing himself upon grounds of "delicacy," and saying as little as possible in regard to living architects and their productions, that in speaking both of the one and the other, he goes to an extent quite unprecedented, except it be either in anonymous criticism, or hostile literary controversy. Neither is there any thing apologetic in his tone; he does not offer his opinions as merely those of an individual, but as positive and unquestionable dogmas, no less implicitly to be adopted than they are fearlessly proclaimed without the slightest misgiving on his part.

Whether it be altogether prudent or becoming in an individual, let his ability be what it may, to set himself up as a sort of oracle, and to assume a self-elected dictatorship over all the rest of the profession, is a point we leave others to settle. Be it either with or without "right," such is in a manner the case; nor have we to read far in his book before we find, that however unwarrantably it may have been usurped, Mr. Pugin is determined to exercise his office with a high hand. We do not know if this new volume of his is the same in substance with a series of architectural papers announced some time ago under his name, in the *Art Union,* but which never appeared. It is not altogether unlikely, for there certainly is much which not every editor would care to sanction; nor is Mr. Pugin a writer very submissive to editorial control, or disposed to expunge or qualify or soften down what may be objected to as offensive and unsafe opinions and expressions.

Like another Sir Huon, Mr. Pugin plucks a Sultan by his beard, the Sultan in this case being no other than the Professor—aye, the "living" Professor—of Architecture at the Royal Academy, whom he treats not at all more ceremoniously than he did Sir John Soane, when he showed up the "Professor's Own House." "It is a perfect disgrace to the Royal Academy," he says in a lengthy and piquant note, at his third page, "that its Professor of Architecture should be permitted to poison the minds of the students of that establishment by propagating his erroneous opinions of Christian architecture. The influence which his position naturally gives him over their minds is doubtless considerable, and the effect of his instructions proportionably pernicious. Not content, however, with the disparagement of ancient excellence, which he introduces in his official lectures, he is *practically carrying out* his contempt of pointed design in both Universities, and in a manner that must cause anguish of soul to any man of Catholic mind and feeling. The ancient buildings of King's College, models of perfection in their way, are actually being demolished in order to make room for a monstrous erection of mongrel Italian, a heavy, vulgar, unsightly mass, which already obscures, from some points, the lateral elevation of King's Chapel, and which it is impossible to view without a depression of spirits and feelings of disgust. A man who *paganizes* in the Universities deserves no quarter."!

We need not quote further, but may leave the remainder as a titbit in store for those who feel their curiosity wetted, by the "taste" we have given them of this formidable note, merely remarking here that it hints at "gin-palace design" at Oxford, and prophesies that those, and many other works of the present day, "will be the laughing stock of posterity." Still, though we are inclined to admit that the buildings Mr. Pugin so mercilessly reprobates are decidedly bad, yet not perhaps quite so much so as to occasion "anguish of soul," and actual "depression of spirits;" we consider them such, not because they are not of "pointed design," but because they are very tasteless and excessively poor in themselves—strangely crude and patched-up abortions, without any manifestation of study bestowed upon them, and egregiously defective, not only in regard to taste, but as buildings, and devoid of all unity of plan and composition. In falling foul of the professor for "paganizing" in the universities, Mr. Pugin is perhaps rather too severe, and somewhat unguarded, for there has been a good deal of "paganizing" elsewhere before now, and the example was set by the very fountain head of orthodoxy, the apostolic city, and by the very successors of St. Peter. The Vatican itself is most dreadfully and scandalously pagan: its galleries are a perfect rendezvous of heathenism. We are, therefore, at liberty to fancy that, although he has not had the candour to admit as much, Mr. Pugin devoutly damns "Leo's golden days," and the "paganism" of Popes and Cardinals, who, to make use of his own expressions, poisoned the minds of architects, artists, and students of all countries, by propagating erroneous opinions of Christian architecture and art. Certain it is that he could not point to that quarter, to Catholic Rome itself, as a model of Christian and Catholic purity, or else he would most assuredly have done so in the language of triumphant argument: whereas it may fairly be suspected, he is tolerably conscious that the less said on that head, and the more it is kept out of sight, the better, since he would, no doubt, be puzzled to reconcile the gross laxity of Rome, with his own rigorous ultra-Catholicism in architecture. Why, then, does he keep continually harping upon that string? why is he for ever taunting the profession and the public with a reproach which, however well deserved, and how great soever he may consider it to be, cannot possibly have any effect upon either? He tells them that architecture is no longer "the expression of our faith, or government, or country;" and they reply by laughing at him in his face, as a crack-brained enthusiast—an arrant Don Quixote, the champion *à l'outrance* of a chimerical Dulcinea. He lays by far too much stress on what are now regarded matters of perfect indifference, and not without reason so—on the mere externals and paraphernalia of religion, which both have been and are substituted for religion itself where not a particle of the latter exists. The attaching so much importance to the *costume* of devotion is dangerous, for it leads to a species of mummery and mountebankery which disgraces what it professes to honour.

It might be more discreet on the part of Mr. Pugin were he not to dwell so emphatically and so exclusively, on what forms the staple of his writings, and renders them quite as much polemical as architectural. Most certainly we should have been better satisfied had he obtruded upon us fewer of his religious opinions, and favoured us with something more in the shape of tangible criticism. Of the last we obtain but very little; it may, perhaps, be said to be in the "*pointed*" style—and so far appropriate enough: yet it is too bare and indiscriminate, and is in manner what would be termed downright verbiage and flippancy in a reviewer, or a magazine article. By denying all merit to, and endeavouring to convict of absurdity whatever does not belong to the only style of the art he is disposed to tolerate, he overshoots the mark altogether, and deprives his strictures of efficacy. He gives—at least leaves, us to understand, that our former English style is the only one at all suitable for us, and that all buildings in any other, are, without further inquiry into their merits, to be condemned as naught. The consequence is, the sweeping invective becomes a most harmless, if not inoffensive tirade: falling all alike, it affects no one in particular more than another, but leaves all, the best and ablest as well the most imbecile and the meanest, involved in the universal disgrace. So that the latter may even take consolation to themselves, by finding that their superiors are brought down to their own level, and made to appear just as incompetent as themselves.

With respect to Mr. Pugin's remarks on what has been done in architecture within the last twenty years, we do not complain so much of their severity and of want of patriotism, as of the indiscriminate censure manifested in them. It would seem, that all is bad alike—that is nothing for exception—that the Italian style is quite out of place in the Travellers' and Reform clubhouses, and treated without either propriety or *gusto*. We cannot, indeed, for a moment suppose that such is really Mr. Pugin's opinion—for in that case his opinion would be perfectly valueless, but what he says implies nearly as much, though he has reserved to himself the power of explaining a good deal of it away by saying that it is to be understood in a qualified and limited sense. At all events, what he does say, amounts to little more than the expression of uniform disapprobation: let him make what exceptions he may, he reserves those for the ear of his father confessor, who is not likely to divulge them. While, however, we agree with him that, notwithstanding the enormous sums they have cost, many of our public buildings are decided architectural failures, we are of opinion that the mischief is not so much to be attributed to the style adopted for them, as to the incompetence and want of artist-like feeling with which it has been treated. We are far also from believing that the style, so exclusively advocated by Mr. Pugin, would have been at all more appropriate or more efficacious, in the majority of the instances alluded to. The merely adopting a style does not confer genius; so far from it, that were we to judge of any particular one by the use which is made of it, we should be compelled to confess that the "pointed" is the most barbarous a balaam style conceivable, according to a great many modern samples of it.

Not content with advocating the claims of the pointed style for ecclesiastical and collegiate structures, Mr. Pugin seeks now to recommend it, exclusively of every other, for modern buildings of all kinds—for street architecture, dwelling houses and shops, although the specimens he gives are not at all calculated to enforce his arguments. Had any one else ventured to propose "Gothic" for shop fronts and windows, he might have been fancied to be quizzing. Nearly arrant masquerade in itself, such a system would tend to deteriorate the style most deplorably. Unless none but *artists* were employed, it would in a short time become a mere parody of the original—maimed, barbarous, and not to be beheld without "anguish of soul," by those who have any feeling for the original itself. No: the present negative style of our street architecture is infinitely preferable, inasmuch as no smell at all is better than a stink. Dull and monotonous as they are, the walls and holes in them for windows which form our streets, are preferable to what the author of the "Apology" recommends; there is no more to admire in them—no more design or variety than in the pavement itself, but there is also nothing to offend, nothing that solicits notice merely to disappoint and disgust.

There are, indeed, particular occasions where the pointed style might be applied, not only with propriety and consistency, but with admirable effect, although they have not been referred to by Mr. Pugin;—we mean, covered markets, and covered avenues of shops. For the former, an open timber roof would be perfectly in character, while a cloister gives us almost a direct model for a Gothic "arcade," requiring no further modification than as regards matters of detail. In such cases, while the design could be kept up consistently, without the slightest interference from individual fancies and caprices, there would be nothing to detract from or neutralize the effect of the ensemble—nothing to clash with it—nothing "over the way," altogether different in physiognomy to jar and jumble with it, in preposterous discord. For houses in the country, the Gothic style is sufficiently accommodating: they are generally built for the actual occupiers—at least for the family to whom they belong, and allow of greater study being bestowed upon them, and the style being properly kept up; but widely different is the case with houses built by wholesale as mere trading speculations. Supposing that indispensable detail, string-courses, copings, weather mouldings, &c., added nothing to the expense, and that carved decoration could be had for very little, yet family devices, heraldic ornaments, mottos and legends must be omitted, unless they could be changed with every change of tenant, since otherwise their incongruity—supposing such things to have any meaning at all, might occasionally prove more ludicrous than agreeable. We might further object that the lofty roof and gable shown in one of the specimens for domestic or street architecture at the present day, would be far from being any improvement upon the system of building now in vogue. Undoubtedly such things tend to give character externally, but then it is after a manner almost at direct variance with the normal principle laid down by Mr. Pugin himself—that every building should be natural, without disguise or concealment, and that nothing should be introduced that does not recommend itself by obvious propriety. It cannot, indeed, be said that in this case there is any disguise, yet there is surely the other error of loading a house with a steep roof—the rooms within which can evidently be but mere garrets—merely because it produces a better effect. Experience has taught that such pitch is quite unnecessary—at least for mere dwelling houses; therefore, to re-adopt it again, would be somewhat preposterous, since it is certainly attended with increased expense—and perhaps with no inconsiderable increase of danger too in case of fire, unless it be intended that iron should be substituted for timber, because otherwise the flames would quickly extend themselves along a whole range of lofty timber-framed roofs.

If such roofs therefore be, as Mr. Pugin will probably contend, so essential to the true character of the style, that it cannot be properly kept up without such feature, it then becomes a very natural question: "Why seek to bring into general use again a style which is so ill-accommodated to our actual wants and purposes, that it will not admit of being modified according to them?" We hardly know if we are to assume as a matter of course that it is intended the interior character should be in perfect keeping with the external elevations, and not only in regard to the architecture and fabric itself, but fittings-up and furniture. That is a point which Mr. Pugin passes over altogether, without giving us any kind of remark, instruction, or caution relative to it; and yet it is one which calls for them all, it being one in no small degree embarassing. It is true the Gordian knot may be easily cut through, by saying: so that the fronts be of antique and quaint physiognomy, no matter what the inside of the houses be;—they may be in any style, or no style at all. We cannot, however, even for a moment suppose that Mr. Pugin himself would consent to get over difficulties and objections in that way, since that would be converting his elevations into mere "*pointed masks*," and sham architecture. No one knows better than the author of the "Apology," that in order to have all in due keeping, furniture and fittings-up require quite as much study as the architecture itself—perhaps more, at least more research first, and contrivance afterwards, there being few models for our express guidance. No one is more alive to the absurdities and "monstrosities," foisted upon their customers, by cabinet-makers and upholsterers, under the name of "Gothic furniture," for he has indulged in a good deal of bitter pleasantry on the subject, in his "True Principles." Nevertheless, he now recommends what would inevitably lead to greater extravagances and absurdities of the kind; for if they have not been avoided where expense has been no consideration, where superior workmen have been employed, and where more than ordinary attention—albeit not directed by intelligence—has been bestowed, it is but reasonable to suppose that abominations still more flagrant would be perpetrated, were it attempted to render such style of furniture universal.

Important, however, as this portion of his subject is in itself, Mr. Pugin treats it so very summarily that all he says on it does not exceed our own comments, in length. We regret this, because we hoped to find and were curious to learn, how the pointed or old English style, could be peculiarly applicable to "civil architecture" generally, as the heading of the section led us to expect. It is a view of the matter, which while it has hardly been touched upon at all, affords a very wide field for remarks and critical inquiry; we are willing therefore to hope that Mr. Pugin will now pursue it much further, and give us an entire volume or separate essay upon that particular subject. We would further hint to him that his criticism partakes too much of mere assertion and opinion; and he, is withal, apt to bestow too much notice on downright paltrinesses which no one pretends to defend, or on minor defects. He complains for instance, that the kitchen court of Lambeth Palace, into which, it seems, he accidentally found his way, is not at all in keeping with the external elevations, the architect having there laid aside "his gothic *domino*;" whereas, in our opinion, it would have been far more to the purpose to examine the "gothic *domino*" itself, which most egregiously disappointed us when we first beheld it, for it is exceedingly *pale*,—passably enough correct, but deplorably spiritless and insipid.

We would further advise Mr. Pugin in future to give us less ding-dong about Catholicism and Protestantism. It looks as if the professed subject was made a mere "stalking horse" to something else: for aught we know, it may be all very good policy for himself, but hardly for his book. If he really expects to gain converts to his own creed, by any thing he can say in its favour, he must have as good a conceit of himself as the Quaker who undertook a journey to Rome, in the hope of converting the Pope. In his zeal for Catholicism, Mr. Pugin may be very sincere, but the world will not give him credit for being perfectly disinterested; therefore, it might be more discreet in him not to challenge in the manner he does, inquiry into his motives. There is besides no occasion for his going out of his direct and proper course, because that affords ample matter—more than he has on this occasion given consideration to. We shall always be happy to meet Mr. Pugin as an architectural writer; as a polemical one we can spare him, nor will all his pomp of words gain him one convert among Protestants, to "the the trumperies and mummeries" which he identifies with christian architecture, and with christianity itself.

Instruction in Drawing for the use of Elementary Schools. By Butler Williams, C.E., F.G.S., &c.

A Manual for Teaching Model Drawing from Solid Forms, combined with a Popular view of Perspective. By Butler Williams, C.E., F.G.S., &c. London: John W. Parker.

We have not space to enter into any lengthened notice of these works in the present journal, we can only now state, from a hasty glance at both volomes, that they appear to have been compiled with considerable care, and that much attention has been bestowed to render the teaching of drawing less irksome than is usually practised.

English Patents for 1842. By Andrew Pritchard, M.R.I. London: Whittaker and Co.

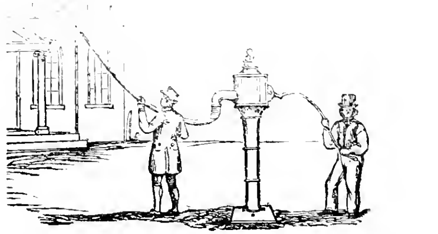
This useful work contains an alphabetical list of all the Patents, amounting to 7089, granted in England during the last year; there is also a classified index, and a concise account of the Law of Patents in Belgium.

Ancient Irish Pavement Tiles. By Thomas Oldham, A.B., F.G.S.S, L. & D., Dublin: John Robertson.

We have already noticed a work on Encaustic Tiles taken from examples in England, to this work the one before us forms an excellent companion, it contains no less than 32 patterns of tiles after the originals in Ireland, existing in St. Patrick's Cathedral, and Howth, Mellifont, and Newton Abbeys. Mr. Oldham, in his introductory remarks, informs us that there are three distinct kinds of Irish specimens—1st, Impressed; 2nd, Encaustic: and 3d, Tiles in Relief.

Turnpike Road through the Potteries.—This contract is let to Messrs. Bowers and Mondy, at about £2 500. The competition was so close that other parties were within fifteen pounds.

ROE'S IMPROVED PUMP.



The improvement consists in that part of the pump called the stuffing box, rendering such a box of no utility, and introducing in its stead a joint composed of leather, or any other flexible substance, such as indian rubber, cloth, webbing, &c. The material employed is cupped sufficiently large to allow the lever of the pump working the piston without any tension whatever taking place.

The joint, it will be perceived from the diagram, is fixed upon the side of the pump barrel, so that when a head is placed on the pump, the head forms an air vessel, and it becomes a powerful fire engine without any extra expense. A, the leather cup shown on section; B, the handle passing though it; C, C, the part by which the joint is secured to the pump barrel. For deep wells this is an invaluable invention, as it is impossible that any leakage can take place; and all acquainted with the common lift pump will at once see the importance of the improvement. By it, also, much labour is overcome, as in the old method in a very short time the rod works a large space in the packing, and much of the water flows back into the well, which, by the new method, is safely brought to the surface. A further important improvement is, that friction is by this means removed. Instead of the piston rod being screwed up tightly in the tow, &c., the rod works quite easily in the joint. One of these fire pumps we are informed has been fixed at St. James's Palace and another at the House of Commons.

DREDGING MACHINE.

Sir.—Perhaps you will allow me to make the following observations in your *Journal* with reference to a letter upon Dredging in your last number, by a person signing himself W. C. And which I think you will more readily do, as it appears to me you have yourself inadvertently misunderstood the improvement intended to be described by W. C.—

You state in your editorial remarks, that "in this *new process*, a lateral "sweep or circular motion is given to the ladder or bucket frame which "swings upon its *upper extremity as a centre*, and in its action imitates "that of a scythe in mowing, &c.;" whereas, *I* do not understand from W. C's. description that the bucket frame has any *such motion* with regard to the dredging machine, but that the whole engine moves radially; the length of the head rope (perhaps one or two hundred yards) being radius, and its anchor the centre of motion.—If I correctly understand W. C's. description, I have to observe that *this* is no new process at all, that this method was adopted at least 23 years ago by Mr. Cubitt (one of the vice presidents of the Institution of C. E.) in dredging a cut of considerable extent in the Ipswich river,[1] and since that time in a new and more complete dredging engine for the Norwich Navigation. The latter machine having been for some time past under my management, I can vouch for the excellence of its working, and I flatter myself that if W. C. had ever seen such an engine he would not have said that the civil engineer has made "no advancement in the working of the machine," a well arranged dredging machine being

[1] Whether this method was first introduced by this gentleman or not I do not know.

already to the civil engineer, what the planing machine is to the engine maker.

I will mention as an instance of the accuracy with which dredging *can* be performed by engines like that I have alluded to, that I have been in the habit periodically of removing a large accumulation of mud with it from the rails of one of Morton's patent slips, touching each rail throughout and leaving the whole clean, and without the slightest injury from one end to the other.

I am, Sir,
Your obedient servant,
George Edwards.

York Chambers, Adelphi,
April 15, 1843.

[We are obliged to Mr. Edwards for his correction; upon inquiry we find that the radius cutting described by W. C. in the last month's *Journal*, is the same as that given by Mr. Edwards in the above communication.—Editor.]

THE SELF-REGULATING EXPANSION SLIDE VALVE.

Sir—In a late number of your *Journal*, I perceive that there is a communication from Mr. H. H. Edwards, of a plan for working steam engines expansively, by means of a plate at the back of the slide valve, which is regulated in the extent of its motion, by means of arms worked by the governor. It is stated that when the plate is held fast by the arms, the steam will be cut off to the greatest extent. Now a very slight examination of the drawings will show that though the steam is cut off as soon as the port of the cylinder is half open, admitting steam during rather less than one-fourth of the stroke, yet on the return of the valve, the port will again be opened, and will allow the steam to pass into the cylinder during the last quarter of the stroke. The same will take place, in a less degree, in every position of the arms until they are at a distance equal to the width of the small ports from both ends of the plate, which is the only place in which they can be of any service, so that of course the plan of altering them by the governor fails.

I am, Sir,
Your obedient servant.

Glasgow, 18*th April*, 1843. Throttle Valve.

FLAX MILL AT CASSANO, LOMBARDY.

Sir—I observe in your excellent number for April, a slight mistake, in an article headed—"Flax Mill at Cassano, Lombardy." Mr. Albano, C. E., of London, is therein stated to be the erector of the works, which may be correct, inasmuch as he was the superintendent of the building of the mill. The mechanical work, that is, the water-wheel and mill-gearing, were solely constructed and erected by Mr. Fairbairn, of Manchester; the greatest credit is therefore due to that eminent engineer in regard to the execution of the mechanical part. *Fiat justitia ruat cœlum.*

I am, Sir,
Your obedient servant,

London, Tuesday, April 4, 1842. S. N. S.

RESPONSIBILITY OF CONTRACTORS.

In the Court of Exchequer, Saturday, April 22, 1843.—*Sittings in Banco at Westminster.*

TOWNLEY, CLERK, V. COLEMAN.

The Attorney-General moved in this case for leave to enter the verdict for the defendant upon facts found by the award of the arbitrators to whom the cause had been referred, or to set aside that award, and for a new trial.

This was an action in which the plaintiff, who is a magistrate for the county of Norfolk, sought to recover damages on behalf of the county from the defendant, who is a builder, under the following circumstances:—The magistrates having determined to erect a bridge near Downham, procured certain plans from an eminent architect usually employed on such occasions, and then advertised for tenders. The defendant became the successful competitor for the job, and, according to the usual course, entered into a contract, to which were attached the plan and specifications. One of the covenants in this contract was, that the bridge should be finished within a specified time, and "kept in repair by the defendant for one year afterwards." When the bridge was completed, the architect and engineer certified that the work had been executed to their satisfaction, and the claim of the defendant was forthwith liquidated by the county treasurer. Little or no repairs were required at the hands of the builder during the early portion of the year, but towards its close the bridge gave symptoms of instability, and just before the expiration of the time, it fell in altogether. When called on to comply with his covenant, the defendant refused, on the ground that the failure of the bridge was not owing to the insufficiency of the work executed by him, but to the inherent vice of the original plan, which, as he averred, was of a nature altogether insufficient and vicious. Not satisfied with this, the present action was instituted, and having been referred to a learned gentleman and two architects, the present award was afterwards made, in which certain facts were found, which fully bore out the above answer of the defendant to the action, and damages were assessed contingently upon the opinion of this Court as to the sufficiency of that answer in point of law. The learned gentleman now at great length urged upon the Court the hardship of attaching the penalty for the architect's defective plan upon the shoulders of the builder, who, *ex confesso*, had honestly and fairly performed his duty. If the plan were of a character which militated against the laws of matter, and was such as to insure its own defeat, it was the fault of the engineer, and not of the builder, whose contract could only be held to extend to a covenant to make good those casual defects which might be caused by wear and tear, or by the insufficiency of his own work. The defendant, therefore, submitted that he was entitled to the verdict on these facts; but at all events he trusted that the award might be set aside, and an opportunity given to him to go down to trial with certain pleas averring those facts on which he relied, in order that the solemn decision of the court of error might be obtained on the case.

The Court, however, without much hesitation, unanimously refused the rule. The law of the case was too clear to admit of a doubt. The defendant bound himself to keep a bridge in repair for a period within which it fell down. *Primâ facie* he was bound to rebuild it, and the only question was whether that construction could be varied by the context of the contract. The language, however, did not appear on examination to admit of such a solution. The defendant had the plan before him, and the specification too, and though it was probable that he confided in the skill of the engineer, and never for a moment contemplated the possibility of the bridge falling down through the defective nature of the plan, yet if he meant to guard against such a state of things, he ought to have done so expressly. It might be a hard case; but the law was so, and the defendant was bound to make good the bridge. With regard to the second branch of the application, it was enough to say that it could never be listened to except in cases of doubt. Here there was no doubt whatever on the bench as to the liability of the defendant, and it would be idle to allow further litigation with such a view of the case on the mind of the Court. For these reasons, therefore, there must be no rule.

Rule refused.

MISCELLANEA.

New Houses of Parliament.—Mr. Barry, Mr. De la Beche, and Mr. Charles H. Smith, the three Commissioners who were appointed by the Crown in 1839, to examine and report upon the quarries of this kingdom, and to select a proper stone suitable for the New Houses, which report is to be found in our journal, vol. 2, 1839, have received instructions to make another inspection of the quarries of Great Britain, both of stone and British marble, and to report upon the qualities of the stone already used in the New Houses, and as to the sufficiency of supply for the remainder of the building, or if there be any other stone more suitable than that now used, either for the exterior or the interior. We anticipate much valuable information in this report, which if only equal to the first, will be received with high approbation by the profession—the three Commissioners have already started on their tour of inspection.

Iron Frigates for the Navy.—We are glad to announce that Government have given orders for the immediate construction of two iron steam frigates, one of 900 tons to be built by Messrs. Ditchburn and Mare, of Blackwall, and furnished with engines by Messrs. Maudslays and Field, and the other vessel, of 1300 tons, to be built by Mr. Laird of Liverpool, and furnished with engines by Messrs. Fawcet and Co.

Steam Navigation in France.—A letter from Brest states that the five steam frigates which are intended for the trans-atlantic navigation between France and the United States, are ready for sea, and will commence service in the spring; and that the French West India Steam Company are going to have a regular line of packet ships between Havre and the Brazils, besides touching at all the West India Islands. The first packets will commence running in May next.

The West India Mail Company's Steamer "The Severn."—This vessel is reported to have made a trial trip at Bristol, from King's-road to Ilfracombe, and it is stated she steamed at the rate of 9 to 10 knots an hour.

The Red Rover.—This fine steam vessel which runs between London, Herne Bay and Margate, has undergone a thorough examination, and considerable increase of speed has been obtained; the engines are by Messrs. Boulton, Watt, and Co. This vessel has always proved to be of the first character.

Norwich and Leamington Railway.—This branch of the Birmingham Railway is about to be commenced and pushed with vigour during the ensuing summer.

The Thames Tunnel.—In the first month after the opening, 450,000 passengers have passed through.

Bristol and Exeter Railway.—This line will be opened to the public in a few days, to Beam's Bridge, two miles to the South of Wellington.

Value of Manure in Large Towns.—A new contract has recently been signed, by which the contractor agrees to give £22,000 per annum for the contents of the cess-pools of the city of Paris, which are at present deposited in a place in the suburbs, called Montaucon, but are about to be conveyed by a new drain five miles further from the city.

Sir John Guest and Co have contracted with the Russian government for 45,000 tons of railway iron, and it is not improbable that this order will be doubled, Turkey.—Messrs. William Fairbairn and Co. have furnished designs for a large building, to be erected for the Grand Sultan in Turkey, for the purposes of a woollen mill, dye-works, &c. It is to be built of iron and wood.

A New Kind of Gas.—The *Censeur*, of Lyons, states that, at one of the late sittings of the municipal council, a trial was made of a new portable gas, to which its inventor has given the name of "hydroluminous." The apparatus, says this journal, is very simple, and applicable to the smallest candlesticks, as well as to the largest and most splendid candelabra. The light it gives is very fine, and it is so portable that it can be carried about with the common hand candlestick. Nothing is said of the comparative cost of this new light.

The Iron Colonnade at Manchester intended to carry the Liverpool and Leeds Junction Railway over the valley at Hunt's Bank, Manchester, is 738 feet in length and 24 feet wide, supported on 52 cast-iron columns, each weighing four tons, carrying 46 main girders, averaging $6\frac{1}{2}$ tons each: on these rest the longitudinal girders 86 in number, varying from $2\frac{1}{4}$ to $5\frac{1}{4}$ tons each, eighteen feet above the level of the street below. The whole will be fenced off on the side next the prison by a cast-iron screen, eleven feet high, the top of which will be seven feet above the rails. The style adopted, and which is in accordance with the massiveness required, is a modification of the Egyptian. The columns, with the mushroom-formed head, from which springs the favourite reeded capital of Egyptian architecture, stand upon stone basements, which project about one foot above the pavement, and give firmness and solidity to the whole appearance. The quantity of iron in the whole structure will be about 1,020 tons.

Bradford Water Works were let to Messrs. Brook and Hardy, for the sum of nearly £6,500.

A very rich vein of lead ore has been discovered at the Shropshire Bog Mines on the property of Henry Lyster Esq.

The grand staircase now building at Devonshire-house will be entirely composed of Italian marble. The estimated expense is £10,000.

An enormous Pumping Engine.—A steam engine is now in course of construction at the celebrated Hayle foundry in Cornwall, for the Government of Holland, to drain the Lake of Haerlem, which is of far larger dimensions than any yet built. We have seen a sketch of the engine, which consists of a double cylinder, one within the other, the external cylinder is to be 141 inches in diameter and 12 feet high, and to have an annular piston with 4 piston rods: in the centre is a smaller cylinder of the same height 84 inches diameter, with a piston rod 13 inches diameter; in this last cylinder the steam is to be first admitted under the piston at a high pressure, and then allowed to escape into the external or larger cylinder, and act upon the upper surface of the piston, the five piston rods support an immense cast-iron cap said to be weighted to equal to 18 tons. The steam cylinders stand in the centre of eleven pumps, each pump is 63 inches diameter, 12 feet 6 inches long, and 10 feet stroke; the present pump rods are suspended to the ends of cast-iron beams 32 feet long placed radially to the centre of the steam cylinders, and the other end of these beams come in contact with the under edge of the steam cylinder cap, so that as the cap descends it depresses one end of the beams and raises the other end, and with it the pistons of the pumps. The weight of water lifted will be equal to 83 tons per stroke, if all the pumps were in work at one time.

LIST OF NEW PATENTS.

(From Messrs. Robertson's List.)

GRANTED IN ENGLAND FROM MARCH 25, TO APRIL 27, 1843.

Six Months allowed for Enrolment, unless otherwise expressed.

Nicholas Henri Jean Francois, Comte de Crony, of the Edgware-road, Middlesex, for "*improvements in rotary pumps and rotary steam engines.*"—Sealed March 25.

Robert Faraday, of Wardour-street, Soho, gas fitter, for "*improvements in ventilating gas burners, and burners for consuming oil, tallow, or other matters.*" (A communication.)—March 25.

Sir Samuel Brown, knight, of Blackheath, commander in Her Majesty's navy, for "*improvements in the construction of breakwaters, and in constructing and erecting lighthouses and beacons, fixed and floating, and in apparatus connected therewith, and also in anchors for mooring the same, which are applicable to ships or vessels.*"—March 27.

John Sylvester, of Great Russell-street, Middlesex, engineer, for "*improvements in producing ornamental surfaces on or with iron, applicable in the manufacture of stoves and other uses, and for improvements in modifying the transmission of heat.*"—March 28.

Arthur Dunn, of Rotherhithe, soap boiler, for "*improvements in treating, purifying, and bleaching fatty matters.*"—March 28.

James Fletcher, foreman at the works of Messrs. W. Collier and Co., engineers, for "*improvements in machinery or apparatus for spinning cotton and other fibrous substances.*"—March 30.

Frank Hills, of Deptford, manufacturing chemist, for "*improvements in steam boilers or generators, and in locomotive carriages.*"

Paul Provost Brouillet, of Hadley, Middlesex, gentleman, for "*improvements in apparatus for warming apartments.*"—March 30.

John Aston, of Birmingham, and William Elliott, of the same place, button manufacturers, for "*improvements in the manufacture of covered buttons.*"—April 4.

Joseph Browne Wilkes, of Chesterfield Park, Essex, Esq., for "*improvements in treating oils obtained from certain vegetable matters.*"—April 4.

George Johnston Young, of Bostock-street, Old Gravel-lane, Wapping, engineer, for "*improvements in the construction of capstans.*"—April 5.

Edwin Whele, of Walsall, Stafford, for "*an improvement or improvements in machinery for preparing wicks used in the making of candles.*"—April 6.

James Boydell, junior, of Oak Farm iron works, near Dudley, iron-master, for "*improvements in manufacturing bars of iron with other metals.*"—April 7.

Robert Hawthorne and William Hawthorne, of the town of Newcastle-on-Tyne, civil engineers, for "*improvements in locomotive engines, parts of which are applicable to other steam engines.*"—April 7.

John Michell, of Calenick, Cornwall, for "*improvements in extracting copper, iron, lead, bismuth, and other metals or minerals from tin ore.*"—April 11.

James Napier, of Hoxton, Middlesex, dyer, for "*improvements in preparing or treating fabrics made of fibrous materials, for covering roofs and the bottoms of ships and vessels, and other surfaces; and for other uses.*"—April 11.

Moses Poole, of Lincoln's-inn, gentleman, for "*improvements in the manufacture of ornamented lace or net.* (A communication.)—April 11.

Uriah Clarke, of Leicester, dyer, for "*improvements in the manufacture of narrow elastic and non-elastic fabrics of fibrous materials.*"—April 11.

William Tindall, of Cornhill, ship owner, for "*improvements in the manufacture of candles.*"—April 11.

William Rumwell, of Bowling-green-row, Woolwich, artist, for "*improvements in machinery or apparatus for registering or indicating the number of persons which enter any description of carriage, house, room, chamber, or place, and also the number of passengers and carriages that pass along a bridge, road, or way.*"—April 13.

William Henry Smith, of Fitzroy-square, civil engineer, for "*improvements in the construction and manufacture of gloves, mitts, and cuffs, and in fastenings for the same, which may be applied to articles of dress generally.*"—April 19.

Charles Tayleur, and James Frederick Dupré, of the Vulcan Foundry, Lancaster, engineers, and Henry Dubs, also of the Vulcan Foundry, engineer, for "*improvements in boilers.*"—April 19.

James Byrom, of Liverpool, engineer, for "*an improved system of connexion for working the cranks of what are commonly called direct action steam engines.*"—April 19.

Carl Ludewick Farwig, of Henrietta-street, Covent-garden, tin-plate worker for "*improvements in gas meters.*"—April 19.

John George Bodmer, of Manchester, engineer, for "*improvements in locomotive steam engines and carriages to be used upon railways, in marine engines and vessels, and in the apparatus for propelling the same, and also in stationary engines, and in apparatus to be connected therewith for pumping water, raising bodies, and for blowing or exhausting air.*"—April 20.

John Rand, of Howland-street, Fitzroy-square, artist, for "*improvements in the manufacture of tin and other soft metal tubes.*"—April 20.

Edward Cobbold, of Melford, Suffolk, master of arts, clerk, for "*improvements in the means of supporting, sustaining, and propelling human and other bodies on and in the water.*"—April 20.

Thomas Oram, of Lewisham, Kent, patent fuel manufacturer, and Ferdinand Charles Warlich, of Cecil-street, gentleman, for "*improvements in the manufacture of fuel, and in machinery for manufacturing fuel.*"—April 20.

James Johnston, of Willow-park, Greenock, esquire, for "*improvements in the construction of steam boilers, and machinery for propelling vessels.*"—April 20.

Richard Prosser, of Birmingham, civil engineer, and Job Cutler, of the same place, civil engineer, for "*improvements in the machinery to be used in manufacturing of pipes and bars, and in the application of such pipes or bars to various purposes.*"—April 20.

John M'Innes, of Liverpool, manufacturing chemist, for "*improvements in funnels, for conducting liquids into vessels.*"—April 20.

Francois Constant Magloire Viollette, of Leicester Square, Middlesex, late advocate, for "*improvements for warming the interior of railroad, and other carriages.*" (A communication.)—April 22.

Richard Greville Pigot, of Old Cavendish-street, gentleman, for "*improved apparatus for supporting the human body when immersed in water, for the purpose of preventing drowning.*"—April 25.

James Moon, of Milman-street, Bedford-row, surveyor, for "*improvements in the manufacture of bricks to be used in the construction of chimneys and flues.*"—April 25.

William Brockendon, of Devonshire-street, Queen's-square, Middlesex, gentleman, for "*improvements in the manufacture of wadding for fire arms.*"—April 25.

William Mayo, of Lower Clapton, Middlesex, and John Warmington, of Wandsworth-road, Surrey, gentlemen, for "*improvements in the manufacture of aerated liquors, and in vessels used for containing aerated liquors.*" (A communication.)—April 25.

Charles Forster Cotterill, of Walsall, Stafford, merchant, for "*improvements in the progressive manufacture of grain into flour or meal, the whole or part or parts of which improvements may be applied to the ordinary method of manufacture.*"—April 27.

John Winspear, of Liverpool, ship-smith, for "*an improved mode of reefing certain sails of ships, and other vessels.*"—April 27.

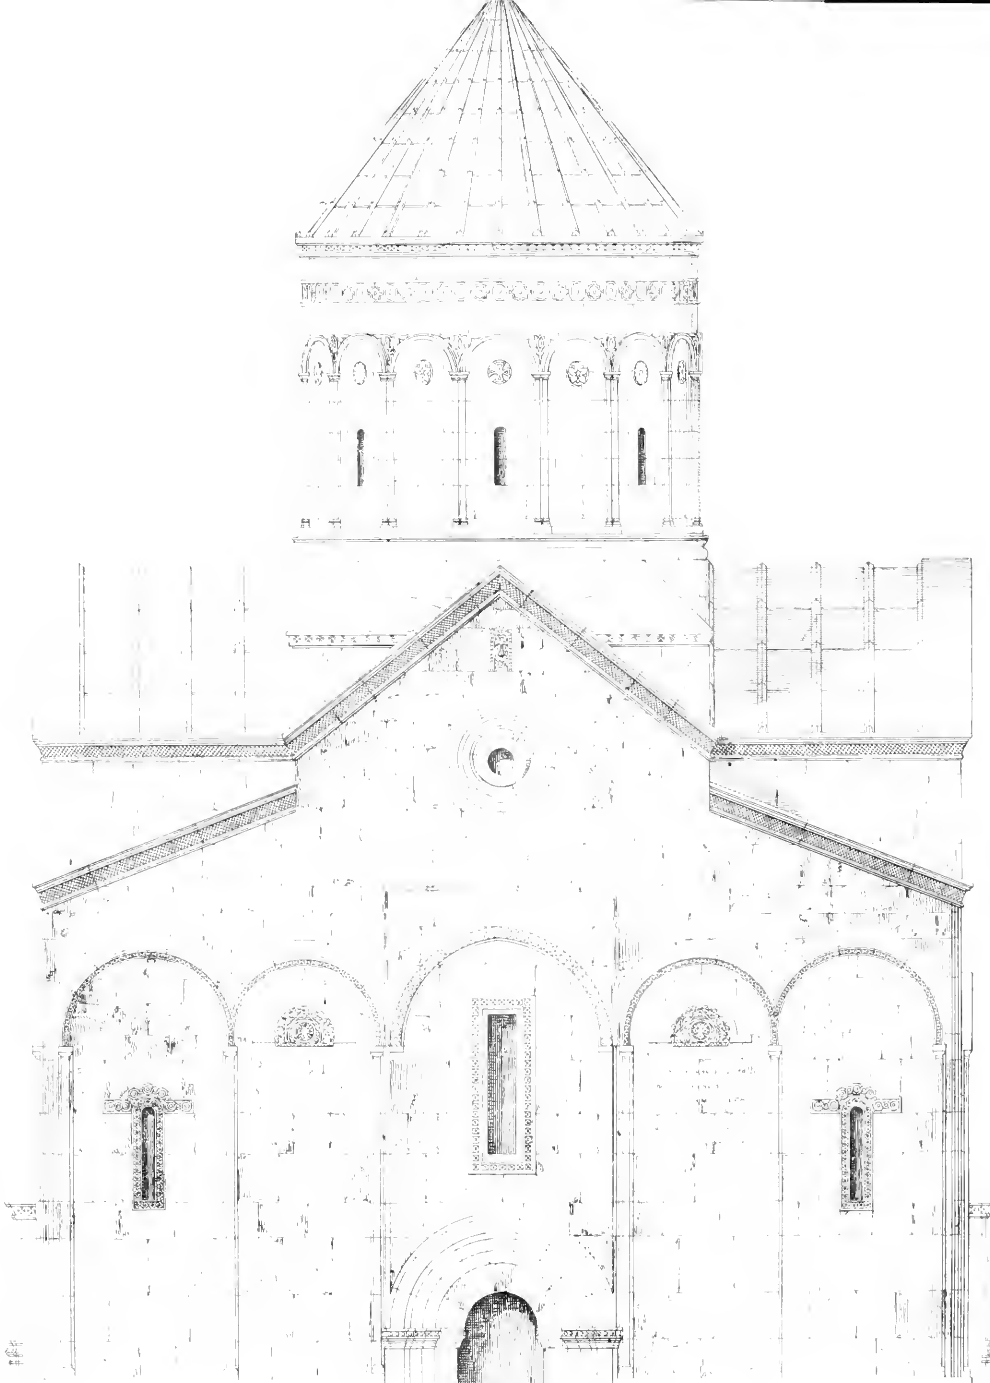


PLATE VIII.

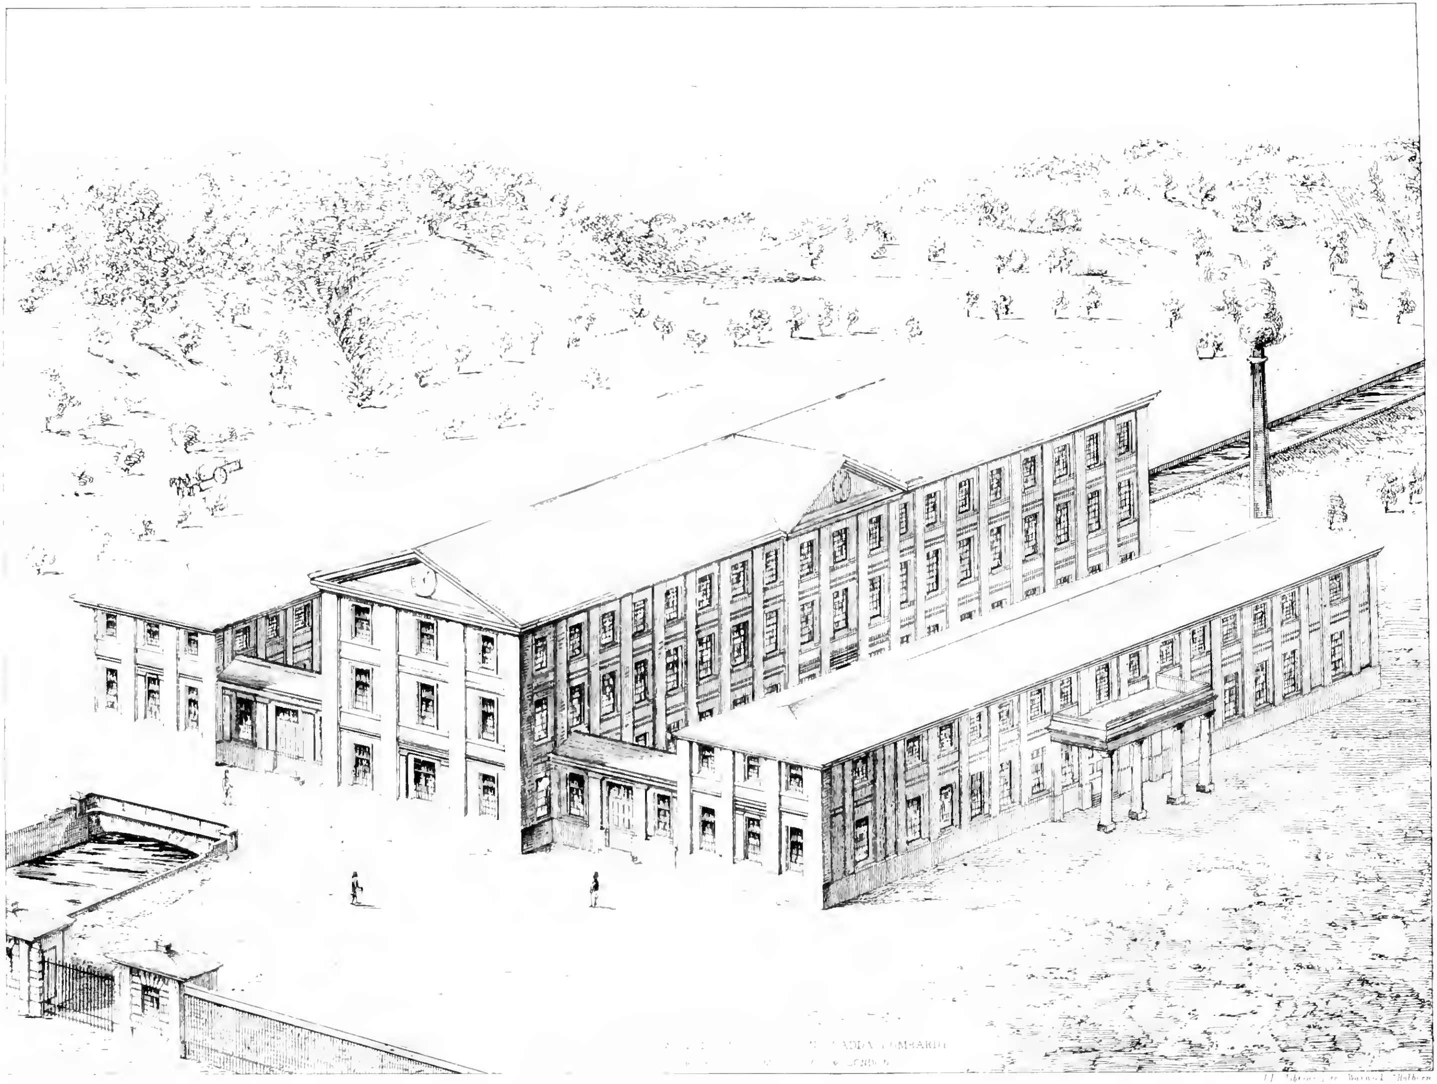

ANI CHURCH IN ARMENIA.

Description of a church at Ani in Armenia, translated from the "Revue Générale de l'Architecture," 1842, p. 102.

(With an Engraving, Plate VII.)

By Professor Donaldson, Vice-President.

(Read at the Royal Institute of British Architects.)

Amongst the ruins of Ani are two churches in an almost perfect state of preservation, upon which Armenian writers have expressed both their censures and praises. We can form a sufficiently correct notion of the extent and character of the monuments mentioned in history. From the enthusiastic manner in which the Armenian authors speak of the metropolitan church at Ani, it would appear that it was considered one of the *chefs d'œuvre* of Armenian architecture, and that this temple was the type of all the religious edifices afterwards erected throughout Armenia.

At the time that the princes of the family of Pagratides were in tranquility, they removed their seat of dominion to Ani. Aschod I. received the royal crown of Armenia from Osdigan Ysa, in the fortress of Ani, in the year 885 of our era. Ten years later, Sempad, his son, added fresh possessions to his inheritance. He was, however, taken prisoner by the Arabs, carried to Tovin, where he died in torture. The throne of Ani was not, however, shaken by this blow; the Greek emperors signed a treaty with Aschod II., and the Armenian princes redoubled their exertions to render Ani a formidable station. Its situation was naturally strong, and they added fresh fortifications. I shall now examine in detail the most important edifices of these ruins. So long as Armenia was addicted to the superstitions of the East, she was the more naturally led to borrow from the arts of Persia, the elements of her national architecture. But when the preaching of Gregory the Illuminator had had its due effect, when the Armenians abandoned their ancient faith and adopted with ardour the Christian religion, a breach arose between the two people, which was signalised by wars and massacres, which terminated in an interested, if not sincere, alliance between the Armenians and Greeks of Byzantium. Whatever concerned the new religion, became an object of common interest to the two Christian nations. The Armenians had, perhaps, outstripped the Greeks, in their submission to the new law, but the ardent spirits of the latter were not satisfied with a mere speculative faith; they built churches and monasteries in all parts of the country, which came within the communion of the faithful. It was like a forcible possession, which the reactions of Paganism sometimes shook, but which they could never recover. We may trace in the progress of Byzantine architecture, the gropings of the first Christians to find a temple, which might give as a whole a striking symbol of Christianity. During five centuries, the Christians sought, without appearing to be satisfied. Hence it arises that in the religious monuments of the four first ages, is found the greatest variety, if not taste. They are, in fact, ancient temples, with the porticos closed to form the nave. At other times all the peristyle of the temple is enclosed within an exterior wall, and thus the Pagan edifice becomes an immense basilica. Some bishops built circular churches, or rather, as at Hieropolis, the church is formed of a certain number of beams simply covered by a roof, such as are now used for warehouses and sheds. After the fifth century, light broke in upon the Christian artists, which tradition expressed, saying that an angel had appeared to Justinian, in order to trace out for him the plan for his new temple, which model has been alone imitated, to the exclusion of all others throughout the whole Byzantine empire. There is no trace amongst the Armenians of this natural progress of an original genius. Being always the vassal empire of a foreign people, it yielded unconsciously to the influence of its neighbours, and adopted their arts and literature. We are unacquainted with the style of the Christian art in Armenia during the first seven or eight centuries of our era. The undecided character of the people was evident in all their compositions. Some of them are, however, not devoid of elegance, but in all there is a deficiency of strength and severity of character. The chief defect among the Armenian artists, was their ignorance of what we may call feeling for proportion, and not knowing how to adopt with propriety the ornaments of the masses of which they formed the decoration. Hence it results that the aspect of their buildings presents a cold and mean appearance, for there is no play of light and shade to give value to the large surfaces which only present small columns, without relief, on which the eye may repose.

This defect was not chargeable to the Byzantines, who generally sought in the façades of their buildings to produce striking effects of light and shade, by placing some harmonious relief between the surface of the solids and voids. The delicacy of detail was generally sacrificed to the mass, the proportions of the columns were rather heavy than slight, and they endeavoured to gain the height by raising the semi-circular arch one-fourth of its diameter above the springing. We recognise this character particularly in the edifices of the period of Basilicus and of Constantine Monomachus. The Armenians evidence in their choice of ornaments, more of the Arab than the Roman taste. All their details are executed with great delicacy. The use of columns is very restricted, they are usually engaged and take the place of pilasters. One of the edifices in the town of Ani, in which is found isolated columns, was constructed during the period when the Arabs were masters of Armenia; it is the monument near to which is a minaret, which I consider the principal mosque. Other columns belonging to the porch of a church, also, have capitals of the Arab character.

Upon surveying the circuit of the walls of the town, we recognise the exaggeration of the chroniclers of the times. Matthew d'Edessa thus expresses himself, in speaking of the royal city: "In 1064 the sultan Alp-Arslan, brother of Toghrul Bey, determined to conquer Armenia, and encamped before the royal city of Ani, which was then in the possession of the Greek Emperors. This town contained an immense population, and a thousand and one churches where mass was said." John Alathir, the Arab historian, records the same fact, but only mentions five hundred churches. "Arslan fixes the siege of Ani in the year 1064. This town was protected by two deep vallies; it contained some magnificent monuments, and one might count in it more than five hundred churches." To judge from the present ruins, it would be difficult to conceive that the number of temples dedicated to the Christian religion exceeded fifty, even including the baptisteries and the altars of cross-ways with their pictures.

But this people, who never had the instinct for great works, were satisfied with admiring monuments which are useful to study as the history of art, but which must not be compared to the edifices of the East, to the vast Latin basilicas, nor even to the mosques of Ismalism, erected by the Turkish or Seldjioukides sultans.

The peculiar character of the religious architecture of the Armenians, is the exclusion of the spherical cupola, which is replaced by a conical ceiling. This species of construction applied to the edifices of Ani, is also found in a great number of Arab tombs, in Cappadocia, which was in the possession of the kings of Armenia for several centuries. As these monuments are of a more recent date than those of Ani, there is reason to believe that the Seldjioukides adopted the spirit of the Armenian monuments.

The plan of the metropolitan church of Ani is composed of a nave, with transepts, in the centre of which is placed a dome, and side ailes. The entire length of the church is 105 feet, and its width 65 feet 6 inches, that is to say, the proportion of the edifice does not exceed those of some of our village churches. The dome is supported by four pillars composed of a group of shafts *(faisceaux)* which run up to the impost, and which are carried up so as to form a Gothic arch.

The lateral arches, which separate the nave from the side ailes, have their imposts at half the height of the large isolated pillars, and the higher arches spring from engaged pillars, the shafts and projections of which correspond with the isolated pillars. The choir is composed of a hemicycle, which is decorated with ten small niches, divided from each other by double columns. The altar is placed in the centre of the hemicycle, as is customary in the Armenian rites. A wooden screen, called by the Greeks *Khangclon*, extended from one extremity of the hemicycle to the other; it is to this screen that the curtains and tapestries, of which mention is frequently made, are attached. To the right and left of the hemicycle are two small sacristies, one to preserve the gospels, the other to contain the sacred vases: such is the simplicity of the plan of this edifice. Its decoration consists in paintings, which, however, time has destroyed: there now only remains in the choir some traces of the figures of the twelve Apostles. The whole of the interior of the church was covered with stucco, which has fallen off gradually. The central lantern is at this time dilapidated, the fragments have accumulated in the centre of the church; it is possible to recognize the greater part of the exterior decoration, and the system of covering is precisely the same as that of a neighbouring church, of which the lantern is still perfect.

The stucco in falling has laid open the stone used in the construction of the pillars. It is a volcanic tufo, which has the property of hardening on exposure to the air. The courses of the pillars are formed of alternate yellow and black stone, which recal certain constructions of the thirteenth century in Italy. This taste of zones of various colours was very general among the Mussulmen of Syria and Egypt. In Cairo, they are still careful to paint on their mosques horizontal bands with slacked lime and red ocre, but in other towns in the East these zones are made with different coloured stones. The first impression which is produced on entering this half destroyed nave, is a feeling of melancholy, on witnessing the nakedness of the stone and the coldness of the lines. The narrowness of the side ailes apparently increases the thickness of the pillars. But painting formerly enlivened these high walls, and the small quantity of light shed on the nave when the cupola was complete, must have given to the interior of this temple a melancholy and austere tone, which was in harmony with the grave character of the people who frequented it.

Those, who have observed the progress of the arts in the middle ages in Europe, will be disposed to consider this edifice as a work of the thirteenth century; it indeed bears the characteristics: but the date inscribed on the portal proves it to be far more ancient, and that the pointed arch was in use in Armenia at the period when the Roman style was the only one which was adopted in Europe.

The façade of this church, constructed with remarkable simplicity and decorated with great reserve, presents, however, an interesting subject, as it may be regarded as the type of the German architecture of the middle ages. It is easy to explain why, throughout this country, is found the dome with the conic roof peculiar to the Armenian architecture. After the taking of Ani by the Mussulmen, a great number of the citizens abandoned the town. They could not retire into Persia, where they would have been received as enemies. The Greeks in Byzantium, being equally hostile to them as the Persians, it was towards the North country they directed their steps. They were received by the kings of Georgia, and spread themselves over Moldavia as far as Poland, where they formed different establishments. All these countries, which were still immersed in ignorance, availed themselves of the knowledge brought to them by these new comers. Although a religious spirit was dominant among the Armenians, they were too timid to make any effort to promulgate their doctrines. The rising Christianity of those countries borrowed of them what they could adopt of their arts, but remained faithful to the ritual of the Greek church. The style of this architecture progressed by degrees towards the North. It was from them that the Russians imbibed their first elements.

The façade of the church is in harmony with the simplicity of the plan. All superfluous ornament is excluded. Slight engaged columns on the face of the walls support circular arches, which are raised a little above their centre. The middle arch, on the contrary, approaches the pointed form. Two semicircular panels to the right and left of the window, present to the eyes of the faithful the image of the cross, placed in the middle of an hexagonal star, surrounded by a foliage of flowers.

The three divisions of the nave are indicated outwardly by a pediment, which adjusts itself with the wall of partition of the cross, and by the two slopes of the roof which cover the side ailes.

This arrangement of the upper part was often employed in the churches of the middle ages in Europe. It is the most simple and logical arrangement. The cornices are composed of slightly projecting mouldings, separated by a rather broad fascia, decorated with a Greek scroll. Below the summit of the pediment there is another bas-relief, in the middle of which is a Latin cross placed in a richly sculptured frame.

This grouping is frequently repeated in various ways on the doors, monuments, and exterior walls. It was not only at Ani that this custom prevailed, the principal towns of Armenia were also decorated in the same manner. Ibn Alather, in his chronicle, makes frequent mention of this peculiarity. The town of Matian Neschin was surrounded by a wall composed of large stones, and ornamented with crosses fixed with lead and iron. The quarries of Ani furnished materials of various colours; they availed themselves of this opportunity to execute crosses in yellow and black mosaic. The façade of the church participated in this polychromatic decoration: but we cannot conceive what induced the builder of the church to work in, in an irregular manner, black and yellow stones promiscuously in the wall of the elevation. The quarries which produced the stones for the church are sufficiently abundant to have furnished all the materials they required. Three windows afforded light to the nave; that in the middle is square, surrounded by a broad framework, the two side windows are hardly wide enough to give light to the side aisles. There is an inscription on one side the door in the Armenian language, which states that the metropolitan church of Ani was built by Queen Gadramia, wife of King Kakig, the first successor of Sempad who laid the foundations of the edifice in the year 1010 of our era.

Hence it appears that at the time the pointed arch was unknown in Europe, monuments of the Gothic style were constructed in Armenia. At Diarbekir there is a very remarkable monument, which is now converted into a mosque, also constructed in the Gothic style. The Armenians call this edifice the palace of Tigranes, and there is nothing to disprove its having been the residence of this prince. The ground floor of this palace is embellished with columns in the Roman style, with Corinthian capitals of tolerably correct workmanship; these columns support a range of Gothic arches. The order of the first story is also Corinthian much enriched; the frieze and cornices are formed upon the principle of the Roman arch in the fourth century; the Gothic arch is, however, mixed up with this architecture, so as to indicate its common use in these countries. Although it is difficult to fix the precise date when the pointed arch was first used in architecture, we cannot form any positive conclusion as to the date of the monument in which it is found. Up to the present time this question is far from being decided, but it is very certain that the pointed arch is of eastern origin, since it may be traced in Mesopotamia long before it was known in Europe.

As to the arch greater than the semicircle, which we are accustomed to regard as Saracenic, it is of such rare occurrence in the West, that its eastern origin cannot be contested. It appears certain that it was first introduced into Europe by the Moors, but it may be observed in the eastern buildings, even before the birth of Mahomet. The Armenian church of Dighour presents a remarkable example of this kind of arches, their curve or rather the elevation of the centre above the line of impost is much more decided than in the church at Ani. It bears the date of 1104.

The lateral front of the metropolitan church at Ani is constructed in the same style as the principal front. The gable end of the cross is enlightened by a circular window, as on the façade: under this window is a kind of tympanum or table with a Gothic arch. This table projects very little, and has no particular decoration. To the right and left of the door there are two very elongated niches, or rather two species of sinkings, which correspond with cavities in the engaged columns. The same adjustment may be observed in the back elevation of the church. But there it is more defined, as it disengages the circular end of the hemicycle from the two side sacristies. This disposition is characteristic of the architecture of Ani. It may be noticed in the other church, which is in much better preservation than the cathedral, but which was not so much esteemed by the Armenians. No traces are to be found amongst these ruins of any staircase, nor of any vaults for purposes of sepulture. It was, however, the custom of the Armenians to inter the dead in churches, for we read in the geography of Vartan, that "the body of Gregory the Illuminator was brought from Constantinople, and was placed in a grave under the four columns of the church." The same author mentions a great number of relics found in the churches and monasteries.

One striking circumstance in this architecture is the ingenious manner in which the inhabitants availed themselves of the materials placed within their reach. The roofing is constructed with an art equal to that, which has produced the finest monuments of antiquity. The large tiles made of lava have their edges turned up at right angles, like the tiles of marble used in the temples; these two ends, applied one against the other, are covered by a continuous capping, and the whole is supported upon a stone vaulting. Hence it arises that in the construction of the edifice no wood has been employed; and although abandoned for five or six centuries, the edifices of Ani have suffered little from the effects of time. It is, in my opinion, a remarkable feature in Armenian architecture, to have been conceived in accordance with the materials so immediately within reach. Wood being scarce in the country, the use of it was entirely excluded. As lime is a substance very uncommon in volcanic formations, they learnt to do without it; whilst tufo of different consistence and divers colours were cut, chiselled, and sculptured in walls and capitals, in columns and vaultings, in great variety.

The century which followed that of the erection of the cathedral, witnessed the decline of the town of Ani, which fell into the hands of the Byzantine princes, who already possessed Kars and Erzinghan. The church, which was situated close to the river, appears to have been consecrated to the Greek ritual, as they had added before the entrance a portico or vestibule, which was always placed in front of the churches of this communion.

The two lower courses only remain of the lantern, but all the other fragments are heaped up in the nave. The lantern has been restored from these fragments, and from those of a neighbouring church which is exactly similar to that of the cathedral. The dressings of the door are also very little injured; the rest of the edifice is in perfect preservation. The whole of the monument is constructed of yellow and black lava.

ON THE CORINTHIAN CAPITAL.

Observations upon the very marked and varied style of composition exhibited in the capitals appertaining to the Temples of Jupiter Stator, and of Mars Ultor, and to the interior of the Pantheon at Rome.

By A. W. Hakewell.

The first and paramount duty of the architect being to select an appropriate form or outline for his building, he next considers the detail, with a view to give to the outline a suitable expression.

It is proposed, in the following observations, to take into consideration the subject of detail only, moreover directing attention to one sole feature of ornamental detail, viz., that triumph of human invention, the Corinthian Capital; with a view then to show how bent the ancients were upon giving expression to their works, in order that these, if it may be so expressed, should speak a peculiar and suitable language, it may be well to cite those admirable examples of the Corinthian Capital, left us by the Romans. But prior to entering upon the merits of particular examples of the Corinthian Capital, it may be allowable to refer to the composition itself, commencing with the account of its origin; and here we are indebted to Vitruvius for a simple and elegant story, the spirit of which, it must be confessed, is quite in harmony with the beautiful object to which it relates, and if not taken too literally, but on the contrary, properly entered into, will be found like most of the allegories of the ancients, to contain an important truth.

We are told that a maid of Corinth having died, her devoted attendant seeking consolation in the last sad offices, collected the favourite trinkets of the departed into a gracefully elongated basket, which she carried to the tomb, and secured there, by placing upon it a square tile; it so happened that a young acanthus shot up close to the spot, and entwined its leaves round the basket,

> "Flexile around its sides the acanthus twin'd,
> Strikes as a miracle of art the mind."
> Theocritus.

that the ends of the delicate stems meeting with resistance from the overhanging stone at the top, bent gracefully down, resolving themselves into spirals, which altogether produced so much of symmetry and variety of form, that the artist Callimachus, who chanced to see the composition, made a representation of it, and reduced it to the Corinthian Capital.

The graceful spirit of this metamorphosis will, of itself, secure to it an abode in our minds, but its utility gives it the greatest claim to our attention; linked as the story is with so masterly an invention in the ornamental department of architecture, it reminds us forcibly that art to be striking, must spring from the contemplation of nature; but not exactly from that species of contemplation inferred by this ingenious tale, which can be viewed in no other light, than as a graceful fiction setting forth the first principles of invention; it is to contemplation of a far more mental and abstracted kind, that we stand indebted for the ingenuity and grace exhibited in the design under consideration; we leave no scope to intellectual vision in this affair, and wholly discard originality, if we view it as a matter of fact; and yet there have not been wanting those who have inserted this story in their works, as a credible manner of accounting for the origin of the Corinthian Capital, whilst others have gone still further, and rendered it ridiculous, by graphically illustrating the subject, presenting us with the whimsical group of Callimachus with his basket of leaves. The inventive faculty requires no such broad hints, nor such palpable suggestions, but suggests powerfully itself, and from the slightest incidents; the primary objects which inspire an artist's thoughts, stand in no nearer relation to his matured conceptions, than do the juices gathered by the bee, to the honey to which she finally converts them.

First principles form the basis of his conceptions, but the power of combining is wholly dependent upon originality of feeling, and when taste and judgment are united to invention, then it is that the objects created assume that natural and easy aspect which prompts us to assign their origin to some production of nature; thus the graceful Ionic capital is said to be in imitation of a peculiar style of female head dress; the groined vaulting in Gothic architecture to the interlacing of the boughs of a grove of trees; and because the Corinthian capital does not exist in nature, we go about to make up a most improbable story, we require a trick, a harlequinade on the part of nature, merely because we are unwilling to admit the truth, and pay just homage to the inventive faculty of man.

While discoursing upon the Corinthian Capital, it may not be amiss to remark upon the simplicity of the design itself—simplicity, that essential quality, the inseparable concomitant of all that is beautiful in nature and art, enters largely into the composition of this graceful work; nothing can be more easily understood than the plan of the Corinthian Capital; two circular tiers of leaves, one tier placed above the other, the centres of the upper leaves, corresponding with the spaces separating those of the lower tier; a stem giving birth to spirals jutting out at each of the four angles, the whole surmounted by a slab, concave on its outer edges, constitute this striking architectural feature; albeit the parts are few, still the effect is great; there is no appearance of effort; this is the result of simple intelligent arrangement. These are the lessons which teach us to value the sentiment so winningly expressed by the poet, when invoking simplicity he says—

progress was a voluntary accomplishment, independent of its support, and not the veritable means of that support itself, determined by the conditions of the case alone. These conditions we have shown to be the *weight* and superficial dimensions of the suspending plane: and by these conditions, in the present case, observing an inclination of 3°, we are referred to a velocity of 240, or more properly 280 miles an hour. A modification of these conditions, involving an enlargement of the surface or a diminution of the weight, is therefore, and absolutely, the only existing means by which any part of this velocity could be *effectually* dispensed with; a modification which, moreover, we showed to be equally necessary to its success in another point of view: the accomplishment, namely, of its descent, consistently with the preservation of human life, or even of the integrity of the machine itself. It only remains, on this head of inquiry, therefore, to make a few remarks respecting the particular *form* which Mr. Henson has adopted for this important portion of his aerial apparatus.

Where so much more is required to be done than can be easily accomplished, and the utmost that we can reasonably hope to arrive at is a very limited reduction of the essential difficulties of the case, a lack of proper economy in the disposition of our resources becomes a grevious error, and inevitably leads to the conclusion that chance or mistaken analogy rather than the legitimate inductions of science have had a share in determining the choice. To those who have not considered the matter or made it the subject of actual experiment, it may not readily suggest itself that the really effective obstacle to the accomplishment of an aerial navigation, upon the principle of the plan before us, consists in the difficulty of constructing a rigidly extended surface, of sufficient dimensions and sufficiently light to answer the purpose required of it. Apart from this there is literally nothing that interferes, nothing that has to be overcome: for in the attainment of this object are merged all the obligations in respect of *power*, which the want of it alone imposes, and which constitutes in its default the existing obstacle to success. The difficulty which is here alluded to, and which, be it observed, is interposed by nature herself, in the essential properties of matter, depends upon the ratio in which weight, or rather, its effects in pressure, increase in respect of the distance at which it is suspended from its fulcrum or point of support, and the impossibility of counteracting these effects by the intervention of any means which do not also add to the forces, by the operation of which their adoption in the first instance was required. The conditions of weight, and consequently the obligations of support, increase, as we all know, in the ratio of the leverage, or horizontal projection; and this with such effect, as very soon to confound the best directed efforts of the most ingenious architect to combine solidity and lightness with extension in a plane of any magnitude that is devoid of extrinsic sources of support. With these inherent and inevitable peculiarities, it scarcely needs to be observed, the main object to be aimed at by those who have occasion to construct a surface in which the qualities in question are required to be carried to their extremest degree, is to have a form for that surface the most compact, in which the largest area is contained within the least remote limits; an advantage which the circular alone of all others is pre-eminently calculated to afford. In Mr. Henson's scheme, however, this has been entirely lost sight of, and, for what purpose it would be hard to conjecture, a form has been adopted, in which the smallest extent of surface is obtained in conjunction with the fullest development of all the natural difficulties by which the case is peculiarly beset. The stringency of this observation will be the more readily perceived when we consider that the utmost amount of surface which Mr. Henson has been able to accomplish, (for we will not suppose he has stopped short of his ability in this most essential ingredient of success,) involves an extension of 75 feet on either side the centre of support, within which limits, had he adopted the circular form, he might with equal facility have comprised an area of exactly four times the extent; the very quantity we have already shown to be the least with which it would be possible to enable it to come with safety to the ground.

Besides this, there is another objection to the shape of Mr. Henson's plane, which deserves to be noticed; namely, the superfluous amount of horizontal resistance to which it is calculated to give rise. The force of resistance, it is well known, depends upon the direction of its development—is greatest when it is perpendicular, and diminishes with the obliquity of the impact. Now the whole of the resistance experienced by the opposing front of Mr. Henson's plane, is of the former description, and consequently the greatest it could by any possibility be made to encounter. Without pretending to form any estimate of the actual amount of this force, we shall merely observe that by the adoption of a circular or even an elliptical form, the greater part of it would have been effectively avoided.

Nor must the question of danger be altogether overlooked in criticising the properties of Mr. Henson's plane. Depending entirely for its stability upon the due strength and tension of the cords by which it is supported, it is easy to see how precarious must be that form of structure which at once involves the fewest number and the greatest length; where the whole weight, situated in the centre, is sustained by levers in one direction only, and where, consequently, the rupture of a single line of braces must be attended with the collapsion of the whole mass and its unrestrained precipitation to the earth.

To complete this survey, we will only add one more objection, which, though we have placed it last, is by no means the least characteristic of those to the charge of which Mr. Henson's plane, in its present form, is liable; we mean the obstacle to its rectilinear motion, arising out of the exaggerated inequality of the forces which it is calculated to develop in its progress. If the opposite sides of the suspending plane be in any way productive of different amounts of resistance in passing through the air, (and no precision attainable by art can prevent this conclusion in some degree,) this difference acting continuously and through the intervention of a lever of 75 feet in length, will create a re-action destructive of the regularity of its progress, which it will require the application of considerable powers to be able effectually to counteract. Supposing, for instance, (what may inevitably be apprehended,) that a dislocation or distension of any of the numerous bracings by which the rigidity of the plane is to be secured, should occur on either side of the machine more than on the other, an alteration in the obliquity of the presentation of the sides must ensue, and a disturbance of the equilibrium of resistance, which if it be only equivalent to ten pounds (and at the rate of 240 miles an hour, the perpendicular resistance upon a single square foot of surface, would be equal to 288 pounds) at the distance of 75 feet from the centre of motion, would influence its course with a diversion equivalent to a pressure of 750 pounds, and acting continuously, occasion a constant tendency to move in the circumference of a circle, only to be resisted by a rudder of suitable dimensions; to the manifest retardation of its speed, and the consequent expenditure of a considerable amount of power.

Why Mr. Henson should have fixed upon this form for the construction of his suspending plane, we cannot pretend to surmise. All we can say is that, if it has been designed with a view to preserve any analogy with the bird whose wings appear to be similarly extended in flight, the design is founded in a mistake. The bird requires its wings to be laterally extended, that they may operate to the greatest advantage in effectuating its propulsion through the air. This purpose, however, in Mr. Henson's plan, is intended to be answered by another expedient; namely, the revolving vanes. To retain the form after the purpose has been superseded, is to defeat not to sustain the analogy designed.

We have not stopped to examine the various modifications which have been proposed in different quarters by way of improvement upon this part of Mr. Henson's machine. Two only of these modifications we would particularize, because they have emanated from, or obtained the sanction of, one justly celebrated for his scientific attainments, and especially in matters relating to the present subject: the first consists in doubling the amount of surface, by placing *two* planes, one over the other; and the second, in the adoption of a conical or curved surface, as it were sunk a little in the middle, instead of one perfectly plane, with a view to escape the oscillations which are otherwise apprehended to ensue. With regard to the former of these, there is no doubt the conception is just; but a closer consideration shows it to be impracticable. We have no hesitation in declaring that it would be absolutely impossible to construct two planes of sufficient magnitude, sufficiently remote from each other to allow them to be freely impinged upon, with sufficient strength to maintain that position so completely as to form but *one* object with reference to the power by which it is to be moved, consistently with any thing like the lightness that would be necessary to qualify it for the purposes of mechanical flight. With regard to the second, if it is meant to propose as a model the plan, of which a sketch is given in the number of the *Mechanic's Magazine* for the 8th of April, the same objection would apply. It would be quite impossible to construct it, or anything like it, of the proper size and strength, within the limitation of weight required by the essential conditions of the case. To which we would add, that we are inclined to consider the provision itself uncalled for. If a plane could be constructed of any form sufficiently light and large to serve the purposes of flight, it would be difficult to prevent it from assuming of itself a form analogous to that proposed. But we are, moreover, sceptical as to the properties ascribed to it, and the advantages which it is said to hold out. The freedom from oscillation which bodies of that form are stated to display in their progress through the air, and for the illustration of which we are referred to the case of the shuttlecock, we conceive arises partly from the additional distance of the centre of gravity below the plane of suspension, (which its form obliges, but does not restrict,) and partly from the diminished resistance it offers to the descent; no very great recommendation, one would suppose, where that propensity is the main difficulty to be overcome. But, in truth, the simplest form in all these cases is the best; and if a circular or elliptical surface cannot be made to answer the purpose required of it, it will be in vain to seek for it in a more elaborate construction or a more complex form. And thus much for the suspending plane.

II. The next in order of the parts of Mr. Henson's aerial apparatus which we have proposed to discuss, are the controlling appendages or fan-like expansions, the purposes of which are, as we are given to understand, to regulate the vertical and horizontal movements of the machine, and present an obstacle to the oscillations to which it is expected to be subjected in its course. And first with respect to this latter purpose, the appropriate instrument of which is a vertical web of considerable superficial dimensions, extending from the front to the back of the machine, bisecting the suspending plane, the mode by which it is designed to operate is, we presume, by the resistance to its displacement, which it would experience in the re-action of the surrounding air. Now this resistance, be it observed, is entirely independent of the particular position of the resisting surface, and would have been equally attainable, had it been horizontally instead of vertically displayed; in other words, had the projector, instead of appropriating to that end a special instrument, made an equivalent addition to the suspending plane. To this must be added, that by a vertical arrangement, an opposition is afforded to the oscillations, which tend to occur in one direction only; whereas, had the latter alternative been adopted, all the oscillations which could occur would have been equally provided against, while at the same time additional efficacy would have been conferred upon that part of the machine where it is most required. To have devoted a large, or *any* portion, of his resources to the accomplishment of a single purpose, and that of doubtful and secondary importance, when it might have been made equally conducive to another, and that most exigent and essential, argues a great neglect of economy in those particulars in which its unqualified observance is absolutely necessary to success, and a disregard, to say the least, of those principles upon which the operation of the chief members of the machine depends. It is exactly as if a person having only two horses, and a carriage which their united efforts were but just sufficient to move, were to keep one of them always in reserve, for the purpose of attaching it behind occasionally, when the carriage was going down a hill.

By the intervention of the second of these controlling appendages, we are likewise informed, is to be governed the ascent and descent of the machine in its onward course, and the mode in which we are given to understand this is to be effected, is by some disposition of it, similar to that of the tail of a bird, enabling it to regulate within certain limits the horizontal inclination of the suspending plane. Now in respect of this, the least we can say is, that it is an expedient equally unnecessary and inapplicable with the preceding. The position of a plane suspended *in equilibrio*, is a matter so readily affected, that he must have strange notions of the conditions of the case, who conceives it necessary to make a provision for the purpose in an extensive and cumbrous apparatus. It is not in fact by any modification of construction or application of special machinery that the object in view is necessarily or properly to be accomplished; but by a disposition of the appended weight equally simple and secure. A few shovels full of coal thrown from the front to the back of the fire, or the transfer of any of the aerial passengers from one part of the car to another, would at any time effect a change in the position of the whole floating mass, far more necessary, indeed, and difficult to guard against than to accomplish; and from the smallness of the angle of inclination, more than sufficient for the purposes which could ever in that behalf be required. For it is not, in truth, by any such modification of the *position* of the suspending plane that the ascent and descent of the machine is to be properly governed, but by a modification of the *force* with which it is propelled. The suspension of the machine *in transitu*, being the result of the development of a certain amount of resistance in the air opposed to gravitation, which resistance varies with the rate, and consequently with the force under which it is generated at a given angle, the conditions of this suspension, affecting the level of the machine's course, follow the exercise of this power; so that having a force equal to the propulsion of the machine at its highest elevation, its reduction to a lower level is the natural and simple consequence of a reduction in the energy of the force employed, and *vice versâ*; any modification in the obliquity of the plane which might be necessary to second this movement, being more than sufficiently attainable by the occasional disposition of the appended weight as before explained.

But the adoption of this device, sufficiently extravagant, even if conceived with a just notion of its effects, becomes doubly preposterous, when viewed in the light of a contrivance, not only unnecessary and inapplicable to the purposes for which it was intended, but absolutely producing its effects in direct contravention of the anticipated results of its operations. For what are the consequences of the modification in the obliquity of the suspending plane, to be brought about by the agency of this caudal appendage, as described by Mr. Henson, in the specification of his machinery, and inconsiderately adopted by all those, without exception, who have taken upon themselves the office of enlightening the public upon this interesting subject? Totally overlooking the circumstances upon which the actual suspension of the machine depends, and regarding it as it were a body endowed with the power of following with equal facility any course towards which it might happen to be directed, all alike concur in considering the disposition of the inclined plane as giving (so to speak) the *cue* to the appended body; so that having attained an elevation in the bosom of the air, all that is necessary to increase that elevation is to augment the angle of inclination, and, *vice versâ*, to diminish the elevation, it is only requisite to decrease the inclination of the suspending plane. Now the whole of this reasoning is false, and the consequences in fact directly contrary to what they are here represented. So far from the direction of the plane indicating and controlling the course of the machine in the way described, paradoxical as it may appear, the modifications in question would be productive of exactly opposite results; as will be evident to those who consider the conditions upon which the support of the plane *in transitu* is really dependent. The resistance developed upon the under surface of the plane and resolved in a direction opposed to gravitation, which is the true grounds of its support, following the ratio of the *squares* of the sines into the cosines of the angles of inclination, while the horizontal resistance, which is the measure of its propulsion, varies as the *cubes* of the sines of the same angles, any alteration in the obliquity of the plane must affect the latter more extensively than the former, and determine a balance in favour of that condition which is most in conformity with the change; if it be to *diminish* the horizontal resistance (which is the result of a diminished angle of inclination), increasing the relative effects of the vertical, which is the medium of support; and if to *increase* the horizontal resistance, (which is the consequence of augmenting the inclination) to disparage the vertical resistance, and incontinently subtract from the ascensive powers of the machine. Accordingly, therefore, if the machine be progressing with a given force, and it be desired to *rise*, this result will be accomplished by *reducing* the inclination of the suspending plane, and on the other hand, if the angle in question be *enlarged*, it will immediately begin to *descend;* the rate in the former instance increasing and in the latter diminishing with the alterations in the obliquity of the plane, and the accompanying alterations in the level of its course.

With regard to the remaining purpose of these controlling appendages, corresponding to the horizontal steerage, of the aerial vessel, but little needs to be observed. Having no forces to contend with which operate to favour one direction more than another, except such as may arise from the unequal resistances occasioned by the opposite sides of the machine itself, any amount of artificial resistance beyond what is thus indicated, if properly applied, is sufficient to give a preponderance to any course which may be chosen; the only advantage of a more liberal supply being in the limitation of the space within which it enables the aeronaut to effectuate his purpose—an advantage of no great consideration in the abundant regions of the sky. In this respect the case of the aerial machine is most favourably distinguished from that of the ship at sea, pursuing her course under the influence of the wind; where the force by which she is propelled being frequently oblique, and in a sense adverse to the direction of her route, she requires a *given* power, not only to *obtain* a course but to *keep* it, and the conditions of which are governed by those of the force to be opposed.

It only remains to observe, in answer to the objections of those who imagine that, in the tenuity of the medium, exists an impediment to the efficiency of the rudder, that these objections are founded upon an imperfect consideration of the principles of the case involved. The impediments to the efficiency of any instrument are equally dependent upon the obstacles to be overcome as the means of overcoming them. Where these arise out of the same conditions, there can be nothing in the conditions themselves to influence in either way the success of its operations. And this is the case exactly with respect to the guidance of the aerial machine by means of the rudder. The obstacle to be overcome and the means of overcoming it are the same—namely the resistance of the air: in proportion as the weakness of this condition operates to disparage the powers of the rudder, in exactly the same proportion does it operate to disparage the forces by which the action of the rudder is opposed.

III. We now proceed to examine the third subject of investigation which we proposed to ourselves in the outset; namely, the revolving apparatus, by the reaction of which the impetus is to be maintained, which is to determine the progressive motion of the machine. These instruments may be most succinctly described as both in form and operation resembling the rotatory portion of a windmill, only consisting of *six* arms instead of *four*, about 10 feet long (the breadth not stated) and inclined to the plane of their revolution at an angle of 45 degrees. Being two in number (one on each side of the centre of gravity) in the same plane, and facing the direction of the intended route, that part of the resistance they are calculated to generate by their forced rotation which is perpendicular to the plane in which they revolve, becomes available to the propulsion of the machine, and constitutes, in fact, the measure and the means of its success. As it is clear, by the obliquity of the impact a certain quantity of the force which is developed becomes resolved in directions not favourable to the object in view, before any thing can be pronounced with certainty as to the efficiency of the means at command, it must be determined how much of these means is really turned to account—how much is realized and how much lost in the process by which it is conveyed from the source to the object upon which it is intended to act.

In determining the efficiency of any system of impinging planes, there are *three* elements concerned in the constitution of the force developed, which require to be considered—the *angle* of inclination, the *number*, and the *size* of the impinging surfaces.

Of these elements there is one only the actual amount of which is independently determinable—we mean, that does not regard the other conditions of the case, but has its *maximum* effect assignable with reference to itself alone—and this is the *angle of inclination.* Whatever this be that may be found to be best suited to the purpose, it will still continue to be the best under all modifications of size and number, rate of motion and condition of medium, which may happen to characterize the case. Now this angle, (that whereat an inclined plane is calculated to develop the greatest amount of resistance at right angles to the direction of the impinging force,) has been already determined, both by mathematical induction and actual experiment, in a strictly analogous case; namely, that of the windmill, in which the conditions both of the object and of the means are precisely the same: for it will not be considered to constitute any difference, whether the plane be impelled against the air or the air be directed to act against the plane. In both cases the object is to develop the greatest amount of atmospheric resistance at right angles to the direction of the impact; and the angle at which this is complete has been established to be an angle of 54° 44′. The arguments, both mathematical and experimental by which this conclusion has been sustained, may be found in most works upon pneumatics; but we abstain from quoting them here, because we have a shorter way, and more open to the comprehension of the general reader, by which the same is ascertainable, and which, moreover, by the almost perfect coincidence it presents with the result deduced from other sources, serves at once to illustrate and confirm the correctness of the general inference. We have already had occasion to observe that the ratio of the degrees of vertical resistance, developed by inclined planes moving horizontally, (which is exactly analogous to that the conditions of which we are now investigating) follows the ratio of the squares of the sines into the cosines of the angles of inclination. Accordingly whatever be the angle of which the sine squared, multiplied by the cosine, is the greatest, the same must also be the angle most favourable for the production of the required resistance. This actual computation enables us to fix at 54° 46′, differing only by *two* minutes from that otherwise assigned; as any one who pleases may verify for himself by consulting a table of natural sines, and applying the test to the corresponding sines and cosines of the angles, differing only by one minute on either side, taking four places of decimals in the estimation of the quantities concerned.[3] By what process of reasoning Mr. Henson was led to adopt, for his impinging vanes, an angle of 45° we cannot presume to conjecture; unless, observing that in the opposite conditions of perfect parallelism and direct uniformity of plane, answering to the angles of 90° and 0°, no available resistance at all was generated, he came to the conclusion that the proper resting place was the half way house between. Be this how it may, by assigning an angle of 45° as the inclination of his impinging planes, he has exactly sacrificed *one twelfth* of the whole amount of his resources, as may be seen by comparing the sines squared multiplied by the cosines of the angles of 45° and 54° 46′ respectively, which are subjoined in the note below.[4]

With regard to the two remaining elements of the case referred to, the *number* and *size* of the impinging planes, the amount of their effects in action being not only governed by an indefinite power of arrangement (being themselves unlimited in extent by any specific terms), but moreover, (in theory at least) entirely subject to the influence of another condition—the rate of their operation, it is clearly

[3] The products of the sines squared multiplied by the cosines of the angles of 54° 45′, 54° 46′ and 54° 47′, are respectively ·38483, ·38488, and ·38477; whence it is apparent that the *turning point* is the intermediate angle.

[4] The sines squared multiplied by the cosines of the angles of 45° and of 54° 46′ are respectively ·35347 and ·38488, which is very nearly in the ratio of 11 to 12.

impossible precisely to define the actual quantities or proportions of each which are calculated to produce the greatest amount of resistance available to the purpose in view. But though we are thus precluded from appointing any specific terms to the size and number, in like manner as we have been able to do with respect to the obliquity of the impinging planes, yet are there certain considerations by which these conditions are affected, and under which a rough estimate may be formed of their efficiency or aptitude to perform the work assigned to them. These considerations are drawn from the properties of the medium, and the obligations of speed imposed upon the aerial vehicle by the already stated exigencies of its support. It is well known and easily conceivable, that when surfaces of any specific dimensions are set in motion, a disturbance of the equilibrium of the density of the air must ensue proportioned to the extent and speed of the impinging planes. Now if the system of planes by which this disturbance is effected, should be so constituted as that they come in succession into the same or adjacent portions of the atmosphere before this equilibrium shall have been restored, they no longer operate in or act upon a medium of equal resistance to that by which the other conditions of the case are governed, and upon the hypothesis of which their own effective power has been calculated; and in fact, if this state of things be extreme, so that either by reason of the proximity of the planes or the rapidity of their succession, they pass over the space allotted to them in the same or less time than the air takes to rush into a vacuum (which is at the rate of about 1339 ft in a second) they would no longer have any medium at all to act upon, and consequently be productive of no amount of reaction, however great their number or their size. To mitigate these consequences there are two modes of proceeding; either to increase the distance between the planes, or to diminish the velocity with which they are impelled. Now to the latter of these we are precluded from having recourse by two considerations; first, by the general consideration that, as *rate* is the condition of impact upon which the actual amount of the resistance of a given plane entirely depends, to subdue the rate is to impair the efficiency of the machine *essentially* and without regard to any particular disposition of its parts; and, secondly, because a rate of motion the highest, probably (if not indeed higher than any) that will be found attainable, is required by the condition of rate assigned to the aerial vehicle itself, which rate must at all events be *equalled* by that of the instruments of its propulsion; for it requires no great process of reasoning to perceive that by no appointment of propulsive machinery can a body be indued with a greater rate of motion than that at which the propelling agents are themselves proceeding; so that it will be readily admitted the contemplated relief cannot with propriety be expected from the diminished speed of the impinging vanes. To increase the distance between them is therefore the only available means of sustaining the propulsive energy of the revolving apparatus, which in a construction of prescribed dimensions can only be accomplished by restricting the number; and the only question that remains for our discussion is, whether this condition has been sufficiently regarded in the plan before us. Now this question can be answered satisfactorily by reference to experiment alone; to experiment, with the particular machine in the process of its construction, or to general experience in operations of the same description. To the former of these, of course, we have no means of referring, but to the latter we have happily some pretensions; and in accordance with that experience, we have no hesitation in alleging a very great redundancy in the number of the impinging vanes in Mr. Henson's propelling apparatus, viewed with reference to the special object for which they are designed. Indeed, so convinced are we of the prejudicial influence which even *one* superflous member in a system of revolving vanes is calculated to exercise over the effective product of their impact, that we feel quite assured that had the number of arms been but *three* or even *two*, instead of six, in each compartment, they would have realised under the prescribed conditions of the case, a very superior amount of atmospheric reaction; perhaps the greatest that with an equal amount of surface it would have been possible to have accomplished. We know that to this it may be answered, that in truth the modifications alluded have been tried, and that it was not until the superior efficacy of the larger number had been attested and approved, that the present arrangement was ultimately adopted. But before we admit any force to this conclusion, we must be satisfied that the experiments upon which it is based, embrace all the modifications to which the conditions of the case are liable; that not only has the proper angle of inclination been equally retained throughout, but that the efficacy of the machine has been tested in all cases at its *utmost speed*, and subject to an equable distribution of surface according to the varying circumstances of the case; for there is no doubt that with a subdued rate of motion a larger number of the *like* planes will produce a greater amount of resistance, or that a larger number of planes will produce a greater amount of resistance than a smaller number of the same planes, where the rate of their motion is not such as to require an augmented interval between them to preserve the integrity of the resisting medium.

And here, in concluding this branch of our investigations, we would just briefly warn our readers against a very common and fallacious mode of regarding the operation of this particular sort of instrument, (which may not inaptly be termed the "aerial screw,") by which many are led to overlook or reason away the obstacle here set forth to its success; namely, that this obstacle, arising from a rapid action of the parts in a circumscribed space, would be avoided by the anticipated result of the operation—the progress conferred upon the machine—whereby they would be constantly introduced into fresh portions of the resisting medium; in other words, that the ultimate success of the undertaking will be an efficient means of removing the difficulty by which that success is mainly threatened. The argument is absurd to a degree. It is a *petitio principii* of the most flagrant character; because, not only is the insufficiency of the grounds of the progressive motion of the machine (the impoverishment of the medium) here set forth as the thing to be cured by the result of its own operation, but, the truth is, the very progress of the machine, apart from the operation of the vanes, is itself a main contributer to that deficiency, the effects of which it is expected to repair, in the withdrawal of the medium by the advance of the body within it, imposing fresh obligations of speed upon the agents of its propulsion to enable them to realise the prescribed amount of resistance. It is an argument not merely in a *circle*, but (if we may be allowed to coin a figure) in a *spiral*, in which the premises are rendered even *less* consequential by the conclusion which they are intended to support.

We have now left, of the questions we originally proposed to consider with reference to Mr. Henson's scheme of flight, the *power* by which the parts are to be indued with motion, and the *principle* upon which a first impetus is expected to be acquired. The insufficiency of the one and the fallacy of the other we purpose to expose in our next number.

NEW FLAX MILL AT CASSANO D'ADDA, IN LOMBARDY.

(With an Engraving, Plate VIII.)

We give in this number a plate showing a perspective view of the Flax Mill at Cassano in Lombardy, erected under the immediate direction of Mr. Albano, C. E., of London, and which at present is exciting much attention on the continent. To us it has additional interest, as attesting the wide diffusion of English industry, the whole of the millwright work having been supplied from the works of Mr. W. Fairbairn of Manchester, after the designs of Mr. Albano. It serves to show at the same time the field of employment open to the English manufacturer, and the resources available to foreign enterprise, who are thus able to carry out their own plans, and to profit by the proficiency and talent of the best factories in the world.

The following description of the manufactory we extract from a report of Giulio Sarti, the government engineer, who with his colleagues surveyed the building at its completion, on the 31st of December last.

"The general plan of the manufactory consists of three buildings a large one in the centre containing three floors, and two lateral of two floors each; one of the small buildings serves to deposit and to prepare the raw materials, the centre one for the spinning, and the third for power-loom weaving. This separation into three buildings is requisite, by the diversity of the processes to be worked, which could not be mixed together in a single building. The ground floor of the whole building contains an area of nearly 10,000 square feet, and are constructed fire-proof; of this, the main building is formed of two rooms, with a central staircase, the interior dimensions of each being 90 feet in length and 45 feet in breadth, with 16 columns in two rows, 14 feet in height, of granite shafts and cast-iron Doric capitals, supporting cast-iron beams, and brick vaults. The first floor is formed of two rooms with cast-iron columns 12 feet 6 inches in height, with tasteful Egyptian capitals, and a floor above it, 12 feet high, in the roof of which advantage has been taken to make reel rooms, which are very convenient in a large manufactory. In consequence of the superior arrangements of the building, it is capable of containing 8000 spindles. The motive power of the whole manufactory is an hydraulic breast wheel, worked by water taken from the river Adda, which runs through the building, and has a fall of 9 feet; this wheel is a stupendous piece of mechanism, fit for a model to any manufacturing establishment of the kind. It is 16 feet diameter and 21 ft. wide, the whole of cast and wrought-iron of about 36 tons weight; she takes and discharges the water with the most perfect regularity: on each side there is a large tooth segment, each working a pinion, which transmits the motion to the three different buildings. The regular speed of the wheel and transmission of motion are regulated with true perfection, and the mode in which the fixings and supports are fastened to the buildings is such as to guarantee their position unalterably.

"The cast-iron sluice, which admits water to the channel, prevents anything floating into the wheel; the cast-iron cistern and shuttles, (which supply the water to the wheel, according to the greater or less number of machines at work,) together with the speed of the wheel, are regulated by a centrifugal governor; the elevating machines which carry the whole work from one floor to the next above it, the means to supply the boiler with water, and the fire-pump in case of fire, &c., are all improvements which manifest the superiority of such an establishment.

"The spinning machines were chosen after mature consideration, among those possessed by the most celebrated spinning establishments in Europe, that can give in the greatest quantity and finest work, and among these, the preparing ones are admired for containing the most recent improvements."

We regret that a misunderstanding arose as to the original designs of the machinery, in consequence of a letter signed S. N. S. in our last number, wilfully misrepresenting the facts. On the present occasion we beg leave to call attention to the following correspondence, fully asserting and confirming Mr. Albano's claims, which ought never to have been disputed.

Sir—My attention has been drawn to a communication signed S.N.S. in the last number of your interesting *Journal*, page 181, relating to the Flax Mill at Cassano in Lombardy, in which the anonymous writer commences by attributing to you a slight mistake, by stating in a preceding number, at page 113, that Mr. B. Albano, C. E. of London, was the erector of the works, in order to subjoin the gratuitous assertion, that Mr. Albano was the superintendent of the building of that mill, whilst the mechanical work, mill-gearing, &c., were solely constructed by Mr. W. Fairbairn of Manchester.

In the name of justice, Sir, which has been scandalously invoked by S. N. S. in utter disregard of truth, (and as Mr. Fairbairn promptly wrote to Mr. Albano, saying "*I beg to state, that I am in no way connected with such a communication, nor do I know anything of the writer*,") I beg to submit to you a short account of the real facts of this case, in which I have been acting as agent in this country for the proprietors of the said mill, and consequently I am fully qualified to place all parties in their right position.

As far back as 1839, I have been commissioned by the director of the said proprietors, to procure of several professional gentlemen in Belgium, Leeds, and London, information and estimates for the construction of a flax-mill, and to that effect I applied also to Mr. B. Albano, who furnished full particulars. His plan and report having met with the sanction of the directors, I was further requested to send Mr. Albano to Milan, in order to survey and fix on the proper site for the establishment, which he did, on the express condition, that the direction and execution of the whole work should be entrusted to him without any interference, and accordingly he completed in Milan the required plans, and obtained full sanction thereto, with ample power to execute the work according to his own design.

This preliminary will, I trust, be sufficient to contradict the first part of S. N. S.'s assertion, and I can easily prove the second part equally wrong, when I inform you that upon Mr. Albano's return from Milan, specifications of the required millwright work were sent out to several manufactories in London, Manchester, and Dundee, for their estimates, and on Mr. W. Fairbairn calling at Mr. Albano's office, the plans were shown to him, in my presence, to which he suggested some organic alterations, but on Mr. Albano's observing that they would increase the expense, and be otherwise objectionable, were soon set aside, and Mr. Albano, then proceeding with his own plan, in all its details, chose, with due regard to perfection and economy, to give the order to Mr. W. Fairbairn.

To that effect a contract was entered into, the first clause of which stands thus: "With the sanction of B. Albano, Esq., C. E. Directing Engineer of the said Company, &c., the machinery contracted for in the present agreement will comprise the following articles of millwright work, &c., for the organization of the flax and hemp mill of the said company, now in progress of construction at Cassano in Lombardy, under the immediate direction of the said engineer, B. Albano. The whole of the following millwright work apparatus, &c., are to be executed strictly according to the disposition shown, and dimensions marked, in Mr. Albano's drawings, Nos. 1, 2, 3, 4, 5, 6 and 7, and the following specification respectively signed by Mr. W. Fairbairn, contracting party, and the above engineer."

The mere quotation of the clause demonstrates, that the merit of the designs for the whole machinery alluded to belongs solely to Mr. Albano, and I may further add, that the whole design is different from the mode generally adopted by Mr. W. Fairbairn in constructing mills, as the architectural style, proportions, &c. of the buildings, and arrangement of the water wheel and machinery, are essentially original and distinct, erected under Mr. Albano's immediate direction, and pronounced by the body of Government engineers (whose report of their official inspection of the mill I beg to enclose) to be replete with great ingenuity, and conferring the greatest credit to the directing engineer.

The directors likewise, highly satisfied with his ability, energy, and personal assistance, from the commencement to the last, testified their gratification on the starting of the mill by presenting Mr. Albano with an elegant and valuable gold snuff box, bearing an inscription to that effect, and intrusted to his care fresh extensive orders.

Having so much trespassed upon your indulgence, I shall trust to your kind desire to do justice to all parties, the insertion in your publication of this statement of uncontrovertible fact.

5, White Hart Court, City, May 22, 1843.

Your obedient servant,
Henry Pagani.

Sir.—My attention has been directed to a letter signed S. N. S. in your last *Journal*, wherein it is stated that Mr. Albano, C. E. had appropriated to himself nearly the whole, if not the whole of the merit belonging to the erection of the Flax Mill at Cassano.

Now, in justice to that gentleman, I beg to state, that I know nothing of the writer of the letter above alluded to, and although I may have assisted Mr. Albano in the mechanical arrangements of the mill, I must nevertheless disclaim any connexion with the original project or designs which were exclusively his.

I am, Sir,
Your very obedient servant
Manchester, May 17, 1843. W. Fairbairn.

SUBSTITUTE FOR GLAZED FRAMES IN HOTBEDS.

In the *Rheinlandische Gartenzeitung* is described a substitute for the glazed frames of hot-beds and green-houses, which deserves the attention of florists. Instead of glass the frames are covered with a fine white cloth of cotton. In order to render this more transparent, and enable it to resist moisture, it is covered with a preparation, the ingredients of which are four ounces of pulverised dry white cheese, two ounces of white slack lime, and four ounces of boiled linseed oil. These three ingredients having been mixed with each other, four ounces of the white of eggs, and as much of the yolk, are added, and the mixture is then made liquid by heating. The oil combines easily with the other ingredients, and the varnish remains pliable and quite transparent. The expense of a forcing bed arranged in this manner is inconsiderable, and it yields at the same time many other advantages. Such a hot-bed needs not the anxious attention required by the ordinary one covered with glazed frames. During the strongest rays of the mid-day sun they do not require any particular covering or shade; the atmosphere therein preserves a nearly equable temperature almost the whole day, and requires only to be changed from time to time, according to circumstances. If such a bed is provided with a soil of horse-dung, and a proper thickness of some fertile, finely sifted heath mould is spread thereon, layers of all sorts of flowers, early vegetables, and other plants, may be reared from seeds in it.

CANDIDUS'S NOTE-BOOK.

FASCICULUS XLIX.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. Many others besides myself have, no doubt, frequently been not a little disappointed, on finding how very poor a building, that has promised tolerably well during its progress, has eventually turned out to be. So long as it was encumbered with scaffolding, and nothing could be made out distinctly, there was room for the imagination to work upon it; but when all is cleared away, then also does the poverty of the design become exposed to view—all faults and defects become apparent; and perhaps you find that when completed, the structure is altogether *unfinished*. Yet "*finish*" is one great secret—and truly a far greater secret than it ought to be, in architectural composition. Nor is "finish" to be confounded with decoration, for there may be the first with little of the latter; and a very great deal of the latter, with nothing at all of the first. Without finish, decoration generally looks trumpery and meretricious, and what is intended for simplicity, shows no better than inconsistent parsimony, and therefore shabby meanness. In fact, finish is essential to simplicity; and of this, Grecian architecture might long ago have convinced us, had we studied it in an artist-like spirit, instead of merely consulting its orders as so many patterns of columns. One rule worth a hundred of those usually given in architectural books, is, never attempt a higher degree of decoration than you can finish up to in every respect; since otherwise, do as much as you will, the ensemble will always be unsatisfactory. There may be both tasteful ideas and beautiful parts—but they will be only parts, causing by their very beauty all the rest to displease. Attention to what seem trifling matters, is a most important matter itself in architectural design, for it frequently constitutes the chief difference between what is excellent and what is poor—between what is captivating and what is dull commonplace. Yet because it happens to be what people call "*Only that*," little regard is paid to it, although the *onlyness* of it, renders the neglect of it all the less excusable. Oh! if we had but all the "only thats" which people give us to understand they could easily accomplish, did they but think it worth while to attend to such trifles, how very superior we should become in art!

II. Of opportunities in architecture there are two sorts—the most obvious and intelligible one, that of having a building to execute which affords some scope for design or the display of taste—the other, that of being not only permitted but encouraged to treat the subject *con amore*, and to satisfy oneself. To talk of an architect's being left to satisfy himself—though some, by-the-bye, seem to be very easily satisfied with themselves—may sound strangely to those who look upon him as little better than a tradesman—not as a professional adviser in art, but a sort of apothecary, who has merely to make up their own prescriptions; nevertheless, it is so essential an architect should have such liberty granted to him, that he who shows himself indifferent to it, almost forfeits the name of artist, showing himself to be little better than a mere hireling. Of course, this is to be understood *grano salis*, according to the circumstances and importance of the case; neither is it to be supposed that employers and their wishes are to stand for nothing in the matter, as if it were of very little moment, whether they were satisfied or not. Let employers explain their ideas, and urge their own particular views, but let them also listen patiently to those of the artist himself, otherwise they show either that they more than doubt his capacity, or that they shrink from listening to arguments that may convict them of ignorance or of obstinacy. Architects themselves, on the other hand, might sometimes profit by the hints and remarks of their employers, and should feel rather inspirited—certainly not discouraged, when they find their designs strictly scrutinized, instead of all their merits being detected at a glance; in which latter case it may be presumed the merits are rather superficial and not very numerous. Excellently well it is observed by Chateauneuf: "undoubtedly it is very pleasant to an architect to meet with an employer disposed to give him *carte-blanche* and permission to follow out his own ideas unrestrictedly: yet it is still more delightful to meet with one, who instead of merely passively acquiescing, assents from conviction, after deliberate study of the ideas submitted to him, and from the lively interest he takes in them."

III. Whatever the *Pecksniff's* may think of the matter, certain it is, that though the more obvious features of a style may be copied mechanically by any one, to give the true and the better spirit of the style itself requires an earnest study of it, and a kind of study which instead of being to be got out of books, must be brought to them. That such should be the case is rather consolatory than otherwise, since it proves architecture to have some pretensions to rank as a fine art, not only in regard to the works it produces, but to the mode in which it works. In architecture, very much depends upon conventional forms, and conventional as well as mechanical rules: yet though indispensable in themselves, rules are of little more than negative value: they instruct us to do just that which they can teach any one else to do equally well—and no more. They bring us up to the point where the many stick fast, and beyond which only the few can pass who possess within themselves that finer instinct called genius or talent. Though such opinion may appear somewhat paradoxical, by no means does it follow that a building or design which exhibits the more direct and standard features of the style it professes to be in, gives us the spirit of the style itself; for instead of doing so at all, it may fail to manifest any of its better qualities, and of its latent powers may indicate nothing. Mere correctness and no more, is not much matter for boasting of, the merit attending it, whatever it may be in itself, being but a second-hand one. Much less is it any merit to be correct only in parts—in the commonplace features of the style professed to be followed, while everything else is all but in direct variance with it.

IV. Professor Cockerell has been denounced by Professor Pugin as the man "*wot*" paganizes in the universities, but there was another paganizing Professor before Cockerell at work in them—at least at Cambridge—namely Wilkins, the author of that mass of architectural mawkishness, ycleped Downing College, as which James Wyatt's design would have been as good. Colleges are not built every day, therefore when an opportunity of the kind does present itself, it should be prized accordingly, and made the most of; yet it is lamentable to perceive how often some of the best opportunities have been converted into mere jobs. King's College in the Strand is such an arrant architectural nullity, that its insignificance in that respect shields it from criticism, no one considering it worth while to animadvert upon or even mention so miserable a piece of design.

V. Much as it is the fashion to talk about style and styles, we generally content ourselves with their mere *rincings out*—with sadly deluted, sickly watery stuff, that has neither flavour nor body in it. Of such quality is most of our modern Anglo-Grecian, and our recent Early English. The original spirit is so weakened and rendered so "wishy-washy" by the insipidity poured into it, as to be scarcely perceptible. Yet such dilutions of style are palmed upon us as being quite pure and unadulterated, although they are so only inasmuch as no other spirit or flavour of any kind has been infused into the style nominally adopted; the consequence of which is that we get only the purity of pure insipidity.

BAVARIA.—MUNICH.—THE POMPEIAN HOUSE.—We mentioned in our last the project of the King to erect a Pompeian House near his residence of Aschaffenburg. This plan advances towards realization; the director of buildings, Von Gartner, is instructed to employ the drawings brought by Professor Zahn from Pompeii in 1839, for its construction. It was in this house that the beautiful painting on the walls was found, representing Achilles found by Ulysses among the daughters of Lycomedes; also the groups of fauns and bacchantes, on a blue ground; Hypolitus and Phædra, Ceres, Hygeia, Venus, and Adonis. All these will be carefully copied for the Pompeian House at Aschaffenburg, with the rich bronze altars, marbles, and inscriptions found in the house of Castor and Pollux; so that the visitor will find himself completely in the *domus* of an ancient Pompeian.

ARCHITECTURAL DRAWINGS, ROYAL ACADEMY.

A change has taken place this season in regard to the Architectural Room, inasmuch as it has been removed to the "opposite side of the way," that is, instead of being on the right, it is now the one on the left hand of the staircase; but as both rooms are of precisely the same size, nothing is gained by the change, in point of increased accommodation, and in other respects matters continue nearly *in statu quo;* for we perceive no improvement whatever in the system of hanging the drawings, of which we have said so much on former occasions, that we are sick of the subject. Neither is there, we are sorry to be obliged to say, any improvement at all in the general character of this part of the exhibition—rather quite the reverse—an obvious falling off; and however it may be regretted, this will hardly be wondered at when we find that a very great proportion of those who have hitherto generally contributed to the attractions of the Architectural Room, have this year sent nothing.

The architects want old Soane among them again, to give them a fillip, for as to the present Professor of Architecture at the Academy, the walls might exhibit a blank, it seems, for aught he cares. There was not a single design or drawing of any kind of his last season: and it is just the same now. We do not say that this is very greatly to be lamented in itself, but it is rather lamentable to find that his example is now contagious. It has been followed by Barry, Basevi, Blore, Burton, Donaldson, Ferrey, Poynter, Salvin, S. Smirke, Tite, Wild, and many others whose names do not immediately occur to us. There is very little to inform us what has lately been done, or what is either actually in progress or about to be commenced. Among other things of the kind we had reckoned with some confidence upon seeing the design for the new Conservative Clubhouse, by Basevi and S. Smirke, nor is that by any means our only or chief disappointment, there being, among many others, the new Chapel Royal at Buckingham Palace, which we are bound to suppose well worth seeing. We should like, too, to have found the design for the façade of the British Museum, which we are told is on the eve of being at length commenced;—how we should like the design itself is a different matter—we suspect, not very much; yet, at all events, Sir Robert Smirke has had ample time for studying it, and improving upon his first ideas: nor can he very well fail to be aware that architectural taste has undergone some change for the better within the last twenty or five and twenty years, and that consequently his once admired "classical purity" is not likely to be at all relished—perhaps hardly endured now, but be in very great danger of being voted dull, frigid, and stale common-place. Sir Robert Smirke may be quite as able as ever he was—a rather ambiguous compliment, by the bye—but that wont suffice: what was talent yesterday, is not always looked upon as such to-day: if he has been standing still all the while, others have not; and even the public have now got a-head of him. Most numerous and ample have been the opportunities afforded him during his career—quite equal, with one exception, to Barry's; but he has frittered them all away: and instead of making, as the latter has done, architectural gems out of small buildings—the Traveller's Clubhouse,* for instance—he has made large ones, very little in manner, and exceeding meagre in taste. This, however, is a sort of *par parenthèse*, which our readers are at liberty to skip, and we therefore go on to say that, on the other hand, there are a great many subjects in the present exhibition that we could very well have dispensed with altogether, they being terribly stale, and withal, most unattractive as drawings. Who cares to look at a frame filled with such nothingness as a parcel of Corinthian columns, merely because they are called "The Temple of Jupiter Olympius"?—or at an architectural *bulletin* informing us what was the exact state of the "Erechtheum" last summer? What pretensions, again, have such things as mere architectural portraits—views of buildings in the metropolis, and those tolerably well known—to be admitted into what professes to be an exhibition of original productions, and which, if not strictly confined to them, ought at least to give us only unedited subjects? Exceptions might, perhaps, be allowed in particular cases, where a building that has never been satisfactorily represented before, receives for the first time the attention it merits, and the want of positive novelty in the subject is amply made up for by tastefulness of execution as well as mere fidelity of likeness. This, however, is by no means the case with such things as No. 1187, "Perspective View of St. Pancras Church," or No. 1284, "Interior of St. Martin's in the Fields." If we cannot have what is much fresher and better, far rather would we meet here again with some of the works that have delighted us on former occasions, and to renew acquaintance with which would be refreshening. So impossible is it to discover any sort of system in the management of the architectural part of the Academy's exhibitions, that we fairly conclude there is no system at all, but that the whole is left to "Providence" and the porters. That St. Peter is not one of them, is evident enough, for had he the keys of the architectural room in his keeping, hardly would he admit such architectural Balaam and rubbish as we have seen here hung up; not this season more particularly, but more or less every season. It would seem that any thing in a frame and glass will pass muster so long as room can be found for it, or it serves to fill up an obstinate gap into which no other sized frame can be fitted:—which is by no means a very *fitting* practice in itself; at any rate we would rather encounter a few blanks on the walls, than such prizes. It is really grevious to observe some of the ***Pecksniff*** things that are permitted to show themselves at the Academy, and there stare us full in the face, unless good luck has so well managed both for them and for us, that they happen to be put out of sight. We could mention more than one or even two specimens of the kind in the present exhibition, but the authors of them would hardly thank us for calling attention to them, or feel flattered by coming in for such share of our notice. It is possible that some of the productions of this stamp may be in themselves meritorious, since they may be the works of mere tyros—the first essays of "tender juveniles," who have just learnt to make use of pencil and compasses: but then schoolboy exercises should be kept at home for home admiration, and not publicly paraded, at the risk of being pelted at.

What seems not least of all strange to us is, that there should uniformly be so many things, which professing to be mere designs or ideas, show themselves so barren of ideas—so devoid of any originality either as to conception or treatment. In such cases, it is to be presumed, a design is intended as a display of talent, and to manifest what its author is capable of doing, provided opportunity be afforded him. To produce things of that kind merely to show average taste, and what, if quite as good, is not at all better or more striking than what has been done again and again before, and may be seen almost anywhere, is hardly worth while: nevertheless, we find that it is often done, for be the drawings themselves ever so satisfactory as such, there is very little thinking put into them. Of that description, however, there are very few designs this season—very little in the shape of *Projets*, or what professes to be merely ideal.

Except that it is upon the whole less striking and attractive than usual, it is difficult to say what is the character of the present exhibition, or what class of designs predominate in it. Scarcely ever, indeed, is it possible to form any such general conclusions, or to judge which is the style in particular that seems to be best treated; and this is in no small degree owing to the very great diversity of manner in execution, and the degree of ability displayed in it; for while in some instances things that are rather of mediocre quality in themselves are rendered striking by the taste or spirit with which they are represented, others which are superior as designs, or at least contain superior ideas, are so indifferent as mere drawings as to seem altogether insignificant, more especially when seen along with others, and hastily judged of by the "first sight" impression they make upon the eye. So far, then, an exhibition room is not the very best place of all for forming impartial comparisons, and for judging of the intrinsic architectural merits of the different designs. In order to do that, it would in fact be requisite that they should be all upon the same scale or very nearly so, all in the same style as to drawing and colouring, and moreover, what is not the least impertant matter, that they should all be to be seen equally distinctly. This last, it must be admitted, is almost an impossibility, since, in order to be so seen, they must all be hung upon the same level, that is, just upon the "*line*," and that line would require to be a very "*long yarn*"—about as long as the front of the National Gallery itself, to accommodate the number of subjects we here meet with. Still some little more judgment, or common sense might be exercised than is done at present; and if the suitable accommodation for them cannot be obtained in proportion to the number of drawings, this last ought to be reduced so as to correspond in some degree, with the accommodation.

Of either Grecian or Roman design there is this year very little, though there is at least one of great merit, and all the more welcome because intended for execution, viz. No. 1290, "Interior of St. George's Hall, Liverpool," J. L. Elmes. It is indeed a most noble specimen of Greco-Roman interior architecture, beautifully imagined in its general composition and arrangement, and tasteful and well

* Speaking of this small but certainly not least work of Barry's, the *Polytechnic Review* says, "A chaste specimen of the Italian style, the more it is examined the more it becomes the subject of admiration, and to some almost of adoration. Barry has had the good fortune to have this monument described by the pen of one of the first architectural critics, by one who is no less qualified for any task by the extent of his knowledge than the soundness of his judgment, and who has perhaps done more by his writings for the promotion of sound architectural principles than most men have by their works."

studied in its details, so as to be perfectly homogeneous in character, and to combine sober grandeur with richness, and with a far more than ordinary degree of picturesqueness and scenic effect also. The design, moreover, engages entirely by its own merits, for though carefully and ably executed, the drawing itself is not at all striking or showy, and has not even the ordinary allurement of colour to attract the eye to it. Not always is it that a public structure which is of imposing architectural character externally, presents a corresponding one within; but in this instance the whole will be of a piece, and not only as regards the degree of effect, but also the species of it. In this Corinthian hall, not only is the style of the exterior kept up in regard to the order and decoration, but also in regard to what is a happy novelty in itself, namely, the closing up the lower part of the intercolumns with ornamental screen walls.

Of Grecian design we have another specimen in Nos. 1162 and 1322, the former being "A south-west view of the mansion now erecting at Silverton Park, Devonshire, for the Earl of Egremont," the other of the "Central hall in it," by J. T. Knowles. The first, being placed over a door, is unfortunately too high to allow us to see more than its general composition; for though the drawing itself is of considerable size, the architectural scale is but moderate. Speaking of the mansion, in the last No. of the *Gardener's Magazine*, Mr. Loudon says, "it is eminently classical, abounding in colonnades and porticos without a single vulgar feature externally;" and that there are colonnades and porticos we can plainly see, but that it is therefore "eminently classical" we will not decide, because we cannot make out the other features very distinctly, nor can we judge at all of the quality of the detail. The interior, Mr. L. informs us, he had not an opportunity of seeing, and so far we have the advantage over him in some degree, being here shown what is, no doubt, the most striking part of the interior—perhaps is made rather more so than it ought to be. This "Hall" is carried up the height of two floors, and on the level of the upper one has a peristyle of Corinthian columns. Taken by itself this arrangement is effective enough, though not particularly novel; but we are of opinion that the general design would have been more classical had the lower order in pilasters been omitted. We do not approve of the introduction of two orders, particularly of two such distinct ones as Doric and Corinthian, in interior composition. To us it generally seems to destroy that degree of unity which we naturally look for in an apartment, and to cause its sides to appear too much like external elevations. We think, too, that in the present instance the Doric pilasters carry with them an air of plainness that contrasts rather harshly with the richly decorated and painted ceiling. The best excuse, perhaps, for the introduction of them is, that they serve to divide the walls on which the upper gallery rests, into compartments, each of which is occupied by a large figure on its pedestal (ten of them in all, or five on each side). Though decoration has not been spared, it strikes us that there is a certain poverty of feeling and poverty of form—perhaps owing to the endeavour to obtain simplicity, in some of the separate parts; the doors, for instance, would have borne to be made more important and richer features.

One of the principal subjects in the Grecian style is No. 1197, "Design for an alteration of the National Gallery by effecting, at a small outlay a more imposing elevation."—D. Mocatta. The "small outlay" is somewhat questionable, nor is the alteration here suggested so satisfactory, upon the whole, as it might have been rendered by the outlay of a little—by which we mean a good deal more study upon it; still we think it would produce a decided improvement with regard to the portico and centre of the façade, bestowing on that part of the composition greater loftiness and also greater importance in other respects, though the dome is removed; but that is a feature that can very well be spared, because while it contributes scarcely at all to give the front any dignity in regard to height, it is in itself as insignificant as it is tasteless. In order to increase the altitude of the portico, the columns are here elevated upon a podium added to the present stylobate, by which means their capitals are raised to the same level as the cornice now is, so that the entablature of the octastyle would clear that of the rest of the front. Thus the centre would be more conspicuously marked in the general outline, and the pitch of the pediment being somewhat increased, and bold acroteria and groups of sculpture being placed above it, the augmentation as to height would be considerable, at least as far as effect is concerned. Besides the embellishment just mentioned, the pediment itself is filled with sculpture; and it would, in our opinion, be a further improvement were some enrichment of the kind bestowed on the podium on which the columns are raised; for while it would give the portico a very unusual and here most appropriate degree of richness, sculpture in that situation would show itself to very great advantage, and would serve to give importance and finish to the plain wall or stylobate below the portico, to which it would become an ornamental crowning frieze. Another very considerable alteration here proposed, as regards the portico, is the covering in the ascent up to it on each side, by carrying the steps behind columns so placed as to form wings or loggias immediately attached to the centre octastyle, but retiring the space of an intercolumn. Thus the whole of the centre, if not exactly the portico itself, would thus be greatly extended in breadth, and be rendered a picturesque piece of *polystylar* composition. So far we are very well satisfied with Mr. Mocatta's suggestions, but in his alterations of the rest of the façade he has been by no means so happy. Instead of being at all improved, the windows are made little better than bare apertures, therefore, instead of contributing at all to beauty, tend rather to impoverish and impair the general effect. Of this design we have spoken somewhat minutely, because it possesses, for ourselves at least, an interest of a peculiar kind, being not merely a work of fancy, but an attempt to correct a rather important public building which is now very unsatisfactory in many respects. What is good in Mr. M.'s project seems worth consideration; we should, therefore, like to see a model of the centre compartment on an enlarged scale.

Besides the subjects we have mentioned, there are scarcely any in the Grecian style, and not very many in the Italian; for Gothic of various kinds, Tudor and Elizabethan, greatly preponderate, and of designs for churches, mansions, almshouses, &c., in those styles we find more than the average compliment: and among those for churches are several interiors, one of the most striking of which is No. 1185, "Design for the restoration of the Church of the Holy Trinity, Hull," T. Allom. As may be supposed, the subject loses nothing of its interest by being treated by so able a pencl as that of Mr. A., but it is also an attractive one in itself, and of a character likely to be considered most horribly extravagant by "Church Commissioners." Not knowing what the structure actually is in its present state, we are unable to say what is and what is not the work of restoration; we presume, however, that the fittings-up—pulpit, seats, &c., are entirely so, and they are of a superior kind.

On looking over the catalogue again, and seeing how many names there are of designs for churches, we almost reproach ourselves for negligence in having marked so very few for notice of any kind—either for approbation or the contrary; yet such being the case, it is evident that unless put out of sight, the productions of that class did not strike us as possessing in general more than negative merit—that of being not bad, without being positively good, at least not in regard to any fresh ideas. No. 1247, "Interior of the church about to be erected at Whitstable, Kent," R. C. Carpenter, is of better character than ordinary, plain, but neither impoverished nor tame; on the contrary, marked by considerable vigour of style, and by much pleasing expression. No. 1274, "Design for a church in the Norman style," Gough and Roumieu, shows some fancy, and as represented in the drawing, is a more picturesque composition than usual. No. 1317, "Interior of the Cemetery Chapel erecting at Cambridge," E. B. Lamb, is, though small as a structure, of very superior quality as a design, and is, withal, characteristic of its purpose. Excepting the painted window and the inlaid pavement there is little of actual decoration. Although few, the features are so well marked, so well put together and contrasted, as to give value to each other, and produce a degree of artistic effect, that we could wish to find much more frequently than we do where the means for obtaining it seem to have been far more liberally afforded. This design furnishes an excellent idea for a small private or domestic chapel in the same style.

(To be continued.)

Sinking of the Caspian Sea.—A communication was lately received at the Academy of Sciences from M. Hommaire-Dehel, on the difference of the level between the Caspian sea and the sea of Azoff. Several scientific men have been charged by the Russian government to ascertain the level between these two seas; but the results have differed so much that a verification was necessary, and this was undertaken by M. Hommaire-Dehel, in 1838; but it was not until September, 1839, that he could establish his points of survey. M. Hommaire-Dehel now reports that 18·30 metres is the difference of level between both seas. It results, from the observations made by M. Hommaire-Dehel on the shores of the three seas of southern Russia, at the mouths of the different rivers and streams in the steppes of Astracan, and at the sea of Azoff, that the Caspian sea had formerly a much higher level, and that it was united with the Black sea at a period anterior to any existing historical records. Already this idea as to the junction of the two seas has been maintained, but it was said that the Black sea had become lower by piercing its way through the Bosphorus, and shedding its waters into the sea of Marmora. The sinking of the Caspian sea has been accounted for by the lowering of the basin, but M. Hommaire-Dehel gives an explanation of this, which he conceives more natural, by observing that the Caspian sea has very few tributaries, and that a diminution in the waters of the Oural and the Volga has been a sufficient cause for the lowering of the level of this sea.

ON THE PERFECT VENTILATION OF LAMP BURNERS.

In consequence of the injury sustained by the books in the library at the Athenæum Club, amounting almost to the entire destruction of the bindings; and the complaints of the members of the vitiated state of the air in the rooms, causing headache, oppressive breathing, and other unpleasant sensations; Professor Faraday's attention as a member of the club, was drawn to the subject of ventilating lamp burners in houses; and he was induced to suggest the trial of various plans for affecting the removal of the products of combustion, produced by sources of artificial light. All substances used for the purpose of illumination, may be represented by oil and coal gas; although tallow and wax are also greatly employed, yet as until they are rendered fluid like oil, they cannot be burnt, they may for all practical purposes be classed with it. Now, oil and gas both contain carbon and hydrogen, and it is by the combination of these elements with the oxygen of the air, that the light is evolved. The carbon produces carbonic acid, which is deleterious in its nature, and oppressive in its action in closed apartments, and the hydrogen produces water. A pound of oil contains about 0·12 of a pound of hydrogen, 0·78 of carbon, and 0·1 of oxygen; when burnt it produces 1·06 of water, and 2·86 of carbonic acid, and the oxygen it takes from the atmosphere is equal to that contained in 13·27 cubic feet of air. A pound of London coal gas contains, on an average, 0·3 of hydrogen, and 0·7 of carbon; produces when burnt, 2·7 of water, and 2·56 of carbonic acid gas; consumes 4·26 cubic feet of oxygen, equal to the quantity contained in 19·3 cubical feet of air. So a pint of oil, when burnt, produces a pint and a quarter of water; and a pound of gas produces above 2½ pounds of water; the increase of weight being due to the absorption of oxygen from the atmosphere, one part of hydrogen taking eight by weight of oxygen, to form water. A London Argand gas lamp, in a closed shop window, will produce in four hours, two pints and a half of water, to condense or not, upon the glass or the goods, as it may according to other circumstances happen. Also, a pound of oil produces nearly three pounds of carbonic acid, and a pound of gas, two and a half pounds of carbonic acid. Now carbonic acid is a deadly poison, an atmosphere containing even one-tenth of it, is soon fatal to animal life. The various accidents from lime and brick kilns, from brewers' vats, occasionally from the sinking of wells, as at Cheltenham, and from the choke damp in coal mines, attest the extreme danger contingent upon the presence of this substance. A man breathing in an atmosphere containing 7 or 8 parts of carbonic acid, would suffer, not from any deficiency of oxygen, but from the deleterious action of the carbonic acid. M. Leblanc has recently analysed carefully the confined air of inhabited places, and concludes, as stated in his *Memoire*, that the proportion of carbonic acid gas in such places, may be regarded as measuring with sufficient exactness, the insalubrity of the air; that in the proportion of one part to a hundred of air, ventilation is indispensable for the prevention of injury to the health; that the proportion of carbonic acid gas had better not exceed a five hundredth part, though it may rise without inconvenience, to a two-hundredth part. If a lighted taper be applied to the top of a lamp chimney, it will be instantly extinguished, or a glass jar held over it will become immediately filled with air, in which a light cannot burn. Also sulphurous and sulphuric acid, are contained in the water which results from the combustion of coal gas, and are products injurious to metals and articles of furniture.

It will now be understood, that the object sought to be attained in the ventilation of lamp burners, is the entire removal of all the noxious products of combustion. And with this view, at Professor Faraday's suggestion, the gas lights of the chandelier in the library at the Athenæum, were ventilated by pipes dipping into the lamp glasses, and conjoining at a short distance upwards into one central pipe, which carried away all the burnt air out of the room. In this first practical experiment, many things were learned as to the mode of arranging the pipes; the disposal, when the pipes were very long, of the water produced, &c.; but the objects sought for by the ventilation, were at once and perfectly obtained. This principle may be illustrated by a simple experiment, showing the difference between allowing combustion to give its products to the air of a room, and carrying off these products as soon as formed to the exterior, let a short wax candle be placed burning on a plate, a glass jar put over it, and the upper aperture of the jar closed by a globular cork, through which passes a piece of glass tube, about half an inch in diameter, and twelve or fourteen inches long; the tube descending to the top of the candle flame, and being placed just above it. Under these circumstances there will be plenty of air passing into the jar, between it and the plate, and out by the tube, to supply all that is needed for combustion, and keep the glass chamber sweet; the consequence is, that in this position it will go on burning for any length of time, and the jar remain quite clear and bright; but on moving the cork a little, so that the tube shall no longer be over the flame; all these results will change, though the air way remains exactly as before. The candle will now give the products of its combustion to the general air of the glass chamber, the glass will immediately become dull, from water deposited upon it, the air itself will become worse and worse; the light become dim, and in a few minutes will go out. But if arrested from doing so by the tube being again placed over it, signs of recovering will appear, the light will return to its former brightness, and after a short time, even the dew will disappear from the glass; all in consequence of the proper ventilation of the light. These effects, though striking, may easily be understood by any one who will think of the difference of lighting a fire in the middle of a room, instead of under, or in right juxtaposition to a chimney.

Then came the desire of modifying the system, by removing the ascending flue from its place over the lamp, not from any deficiency in action, but for appearance sake only; and finding that there was sufficient ascension power in the main part of the metal chimney, to allow of a descending draught over the lamp, the tube, in place of going directly upwards, was made to turn short over the edge of the glass, to descend to the area or bracket, to pass along it, and then ascend at the central part of the chandelier, or against the wall if applied to a single light. To this succeeded another form, which is exceedingly beautiful, and appears to be the perfection of lamp ventilation. It is in fact, a beautiful application of the principle of a descending draught to a lamp burner. The gas-light has its glass chimney as usual, but the glass holder is so constructed as to sustain not merely the chimney, but an outer cylinder of glass, larger and taller than the first; the glass holder has an aperture in it, connected

Fig. 1. Fig. 2.

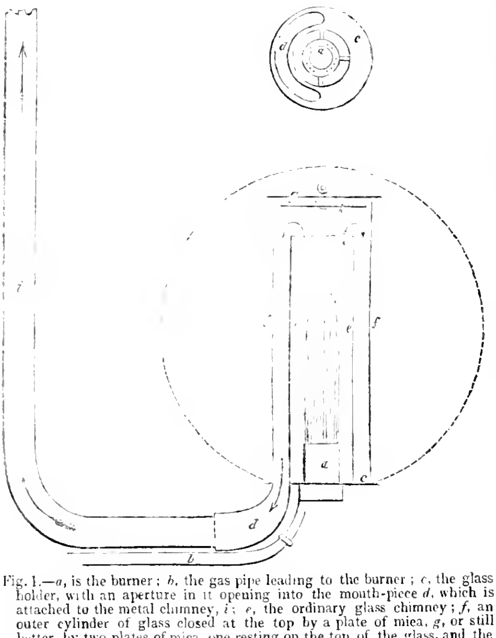

Fig. 1.—*a*, is the burner; *b*, the gas pipe leading to the burner; *c*, the glass holder, with an aperture in it opening into the mouth-piece *d*, which is attached to the metal chimney, *i*; *e*, the ordinary glass chimney; *f*, an outer cylinder of glass closed at the top by a plate of mica, *g*, or still better, by two plates of mica, one resting on the top of the glass, and the other one, *h*, dropping a short way into it; they are connected together by a metal screw and nut, which also keeps them a little apart from each other, thus forming a stopper which cannot be shaken off the glass chimney, but is easily lifted on and off by the small metal ring or knob at the top; *i*, is the metallic tube chimney; *k*, a ground globe, which may be applied to the lamp, and which has no opening except the hole at the bottom, where it rests on the glass holder; but any other form, as a lotus glass or a vase, may be substituted at pleasure.

Fig. 2, is a plan of the glass holder, showing the burner, *a*, in the centre, perforated with jets, with openings round it to allow of a free admission of air to the flame, and the aperture *d*, which opens into the mouth-piece, connected with the metal chimney, *i*.

by a mouth-piece with a metal tube which serves as a ventilating flue, and which after passing horizontally to the centre of the chandelier, there ascends to produce draughts and carry off the burnt air.

The burnt air and results of combustion, take the course indicated by the arrows, and are entirely carried away by the chimney. Now with a lamp burning in the ordinary way, the products of combustion issue out as a torrent of aerial impurity from above, but if the above arrangement be applied, on closing the top of the outer glass cylinder by a plate of mica, all the soot, water, carbonic acid, sulphurous and sulphuric acid, and a portion of the heat, are entirely carried away by the aerial sewerage, and discharged into a chimney or the open air, and the air in rooms may thus be kept in the same sweet and wholesome condition, and fit for the purposes of respiration, as if artificial light were not being used.

A curious but important result of the enclosed lamp, is the increase of light produced, amounting to from 10 to 20 per cent, according to circumstances, the same quantity of gas being consumed as before. If the current of air through a lamp glass, when the gas is burning in the usual manner, be diminished, the flame rises in height, and the light is increased in amount, but is of a redder colour; the combustion in fact is not so intense, because the access of air is retarded; the particles of carbon which give the light, are not so highly ignited, but are more abundant, and are ignited for *a longer time*, thereby causing an increase of light.

The advantages of the above plan are many; it is not in the least objectionable in architectural appearance, the ventilation is perfect, the heat given to a room is modified and pleasant, and may be either sustained or diminished at pleasure; the light, for good philosophical reasons, is increased considerably for a given portion of gas, and increased safety from accidents is obtained; as in the event of any leakage from the pipes, or from a gas cock being inadvertently left open, the gas, instead of mixing with the air of the room, and becoming explosive, would be almost inevitably carried off by the metal tubes.

We understand that Professor Faraday has transferred his right to this invention, to his brother, a gas-fitter, who has secured it by a patent.

REVIEWS.

MODEL DRAWING.

A Manual for Teaching Model Drawing from Solid Forms. By Butler Williams, C.E., Director of the Drawing Classes at Exeter Hall, Professor, &c. Under the sanction of the Committee of Council on Education. London: Parker, 1843.

We have before had frequently to advert to the subject of instruction in design, feeling that we had a double responsibility imposed upon us by our two classes of professional readers; in the first place to advocate the necessity of the proper instruction of workmen, in the next place to watch the interests of art. The want of instructed workmen is a great inconvenience to the professional man—a great obstacle often to the proper execution of his plans, and a knowledge of drawing is essentially requisite in order to enable the mechanic or artizan adequately to execute the designs of his employer. The general progress of art and the creation of a true and sound taste for art, are indissolubly connected with the advancement of architecture and its due appreciation. What is the good of the architect throwing pearls to swine, what stimulus can he have to his exertions from the applause or censure of an ignorant or tasteless mob? The painter, the sculptor, execute their small works for the pleasure of a single individual, or the inspection of a restricted number of visitors; but the architect is called upon to erect monuments which are the delight or disgust of millions. For one man who sees the Loggie or the Sistine chapel, ten see St. Peter's; for one who has the happiness to see Barry's Adelphi pictures, thousands and tens of thousands daily contemplate St. Paul's. The architect, then, has perhaps more at his disposal the means of elevating public taste, than the painter, the sculptor, or even the engraver; it is his to convey those general impressions of art, and that catholic love for it, which the painter and the sculptor are to profit from in their more detailed works. Can we imagine a people living amid the glories of the Parthenon and the other wondrous works of Athenian architecture, without acquiring a deeply rooted sympathy for art—can we suppose men living in sight of the luxuriant monuments of the middle ages, without manifesting a love for beauty of form in every object? We know they did not; we know that the Athenian city, which Pericles built, cultivated every branch of art—we recognize, in the commonest relics of the middle ages, the labours of the artist. When one department of literature is at its height, you have a general proficiency, when one department of art, a stimulus is given to other pursuits. When we had a Shakspeare, then had we Spenser, Jonson, Sidney and Drayton—when Milton, Dryden, Butler, and Denham—when Pope, De Foe, Addison, Swift, and Steele. There is an excitement in a multitude, there is a stimulus in a crowded amphitheatre, which brings out the greatest efforts of the mind; and if you wish literature, if you wish art, if you wish science to flourish, you must not seek to nourish one branch, but to give the greatest scope to all. We therefore cannot pass over in silence anything which so nearly concerns the general interests of art, as the education of the people in design, and the more so at the present period, when an endeavour is at last being made to establish drawing as an indispensable branch of primary instruction.

The work before us is under the authority of the Committee of Council on Education, and published as a text book, which all the schools under their control are to adopt as a normal rule for their guidance. It is drawn up by Professor Butler Williams, C.E., the Director of the Normal Drawing Classes, and describes the course followed in them. It would consequently be well worthy of our examination, if it were only to assure ourselves that the artistic instruction of the country would be properly conducted, but it becomes imperatively necessary to do so, when principles are introduced which appear pregnant with danger to the prosperity and progress of art. With Professor Williams individually, we have on this occasion nothing to do; he seems to have executed the task assigned to him, ably, honestly, and zealously; we shall therefore direct our attention to the system of which he is the expositor.

Among the ancients, drawing was carefully cultivated among workmen, and if we wish to see how extensively and how successfully, we find abundant examples in the unfinished and the complete specimens of the clay vase. Certain it is that the potter of the modern day, is as inferior to his Greek predecessor in artistic proficiency, as perhaps he may be superior in mechanical skill. The use of drawing too was widely spread among the people at large, because among a people uninstructed in writing, delineation becomes both an amusement and a necessity. The Polynesian thus records memorable events, decorates his war-boat, his weapons and his hut, and amuses himself and his comrades with caricatures on the topics of the day. Thus it must be, even among people more advanced in civilization, while unlettered; and if it were on account of the caricature only, design would be resorted to. The numerous examples of this to be found in ancient history, and on the monuments of the people, show how general was the practice of drawing, and what a strong hold it had among the people. We trace this also in the middle ages; we see grotesque sculptures even in sacred edifices; we find satire lurking often in the missal, and we know that commotions were often as much excited by the rude delineations of a Cola di Rienzi, as by the eloquence of a popular orator. Perhaps the general spread of letters no less shook the lower and more popular use of art, than did the Reformation strike mortally at its higher efforts. The player, the ballad-singer, and the news-monger, strove successfully for the annihilation of rustic art, and the grim visages on the corbels, and the rude chalkings on the wall, lost their wonted charm, and with them much of the love of art and of its practice. Certain it is that in the middle ages, art entered more into the pursuits of life than it did subsequently, and into the labours of every artisan. Clothes, weapons, furniture, were more elaborately decorated than they have since been, or than the simpler habits of modern times will ever allow them again to become. It was to this proficiency on the part of the workman, that the mediæval architect was indebted, for the luxuriant finish given to his design, and the rich profusion of ornament which sustained the character of the general conception. How rare, how difficult, has it been in those days, to be able to follow in his step; the machine is the only means of enabling us to imitate at humble distance this luxury of the past. The revival of architecture in England by Wren made this want to be strongly felt, and the establishment of a school of design by Mr. Baptist Lens, as detailed in our *Journal*, (Vol. V, p. 53,) was the consequence. From that time little progress was made until our inferiority to foreign nations and our economical loss, became so painfully manifest as to induce the establishment of schools of design throughout the country. With regard to the Royal School of Design at Somerset House, it was our duty early to point out the gross and lamentable errors in the system of instruction. We then pointed out the danger of copying from drawings, and the necessity of a greater attention to figure and ornament, if we wished to make the establishment useful to the country or the people capable of competing with their foreign rivals. These views of ours and of those who coincided in them, met with the strongest opposition from the Directors of the School, and from artists, and but little attention from the public. They have, however, finally prevailed, and the result is that in the general system of elementary instruction in drawing, propounded by Professor Butler Williams on the part of the government, the error of copying from drawings is strongly reprobated, and is excluded from the plan. The Professor says:

Drawing from Copies.

In the first place we observe, that the pupil is almost universally made to draw from copies.

This fails to exercise the judgment. The drawings which serve as copies, exhibit a symmetrical disposition of lines in true perspective, as also varieties of tint and shadow duly laid and harmonized: they are imitated mechanically by the pupil without his understanding or reflecting upon the means whereby certain effects are produced. His hand alone is exercised; he fails to acquire a habit of observing and seeing correctly, and is unable, after years of labour spent in these purely mechanical exercises, to represent correctly the simplest natural objects. The Chinese cultivate the art of drawing according to this plan; they copy from copies, and produce fac-similies of any work of art; but this is performed solely as a piece of laborious imitation; and their signal failure, when they undertake to design original compositions, is the consequence of the faulty system which aims at training the hand alone to works of the highest skill. High finish in the drawing cannot compensate for glaring inaccuracies of perspective, and even the individual forms, although elaborately brought out, are devoid of expression, exhibiting labour and pains without intelligence, the consequence of following out details without comprehending the scope of the whole design, and of exercising the hand without the guidance of science and understanding.

Drawing from Copies a delusive kind of industry.

Sir Joshua Reynolds, in his Second Discourse, says, "I consider general copying as a delusive kind of industry; the student satisfies himself with the appearance of doing something; he falls into the dangerous habit of imitating without selecting, and labouring without a determinate object: as it requires no effort of the mind, he sleeps over his work; and those powers of invention and disposition, which ought particularly to be called out and put into action, lie torpid and lose their energy for want of exercise. How incapable of producing anything of their own those are who have spent most of their time in making finished copies, is an observation well known to all those who are conversant with our art."

Moreover, the drawings presented to the pupil as models, are not always perfect, having themselves probably been copied from other copies, which may also have been made without direct reference to nature. The drawings of all are more or less characterized by mannerism, and thus, a defect in the original imitation is imitated with care by the pupil.

Exclusive, therefore, of a certain mechanical facility of touch, the pupil acquires little real knowledge by drawing from copies. After years of study, he will be capable of making highly-finished fac-similies of engravings or drawings; and, if he be endowed with a retentive memory, he will have learned a set of unvarying conventional signs for the representation of natural objects in their numberless variations.

The reprobated, the discarded system of drawing from copies, well represented as "a delusive kind of industry," was that adopted in the school at Somerset House, and tenaciously clung to by the Council. It was by the practice of this mischievous system that our artizans were to be brought up to compete with the better instructed workmen of the Continent, and our proficiency in those arts and manufactures where design is used, was to be ensured. It has been our good fortune, alone among the press, to have assisted in exploding it, and it is, therefore, with the greater feeling of confidence we approach the subject of model drawing, which is, in our opinion, no less erroneous and mischievous, and in which we shall, perhaps, find equal difficulty at first in producing conviction on the part of its advocates, though we doubt not of success in the end.

The common practice of commencing the system of instruction by copying from drawings, received its first grand assault from the eloquent pen of Rousseau, in his *Emile*, who proposed, as a substitute, that the child should commence by drawing the human figure from the life. This was considered too bold, and the well-known educationist, M. Jacotot, modified it, by suggesting the study of figures from the antique. Neither of these systems, however, had justice done to it, and M. La Croix, among others, suggested drawing from models of the simple forms. This has been carried out by M. Dupuis of Paris, under whose auspices it has sprung up into a recognized mode of instruction, and has served as an example for the Committee on Education here. This system proposes for models, the delineation of the square, the triangle, the circle, the simple geometric figures, and solids and assumes the merit of greater success, of greater accuracy and greater simplicity. Now such a system is likely to gain many converts among those who have prepossessions on the subject, or who have not had practical opportunities of appreciating its relative advantages and defects. It is very well to declaim on this subject, to talk about analysis and synthesis, but the question is of a mental operation and effect, and there, we opine, individual experience and individual imagination can be but of little value. How little by the examination of our own minds have we been able to learn of the mental organization of mankind; how little has the ability and acumen even of a Dugald Stewart been able to effect; and in what a state of uncertainty are the ontological sciences—indeed, what ought to be the highest science is the most unsettled and obscure. This then should teach us the danger of trusting to individual impressions, and induce us to apply to experience, the only proper and trustworthy guide.

Now looking at the matter in every light, we feel ourselves unable to concur with the judgment of those who have adopted the system of model drawing; we are not convinced it is the best, we are not convinced it is the safest. If drawing were like writing, if it were an assemblage of conventional signs, we should be willing to recognise the necessity and utility of an artificial process for its inculcation, but drawing is an art of representation which admits of the least arbitraries, which addresses itself to the representation of nature, and the earliest efforts of which should consequently be directed in the path of future exercise. We cannot understand *à priori*, and the whole of Mr. Butler William's reasoning on this subject is *à priori* —we cannot understand *à priori*, why nature is to be abandoned in the study of drawing; it will be granted that the ultimate end of drawing is to copy nature, why should not its novitiate be so directed. We have not heard of any valid defections to this obvious course; we have no experience of its impracticability, and we think it at least deserved due attention. Not only then do we believe that drawing from nature is the course in which our efforts should be directed, but we have strong grounds for fearing that model drawing is attended with serious evils. It is well to say that forms in nature are modelled upon the severe outlines of geometrical figures, but such severity is rarely to be met with in the luxuriance of creation. The inculcation then of conventional forms, must be pregnant with danger. What is the mischief of the system of copying from drawings—that it perverts the eye, and renders the pupil incapable of adequately seeing natural objects? The study, however, of natural objects, is a great means of training the eye and the mind. What can we expect must be the result of putting a child through a preliminary course calculated to dull his appreciation and beauty, but to stunt the artistic faculty, and render him less capable of estimating the beauties of nature? That such will not be the result of model drawing has not been proved; and even if the danger be imaginary, care should at least be taken to ascertain that it is so, and not run unprepared into a career of mischief. We, however, say boldly, and we speak from experience, that there is no difficulty at all in teaching a child to draw from natural objects, and no plea satisfactorily proved to us for putting it through an artificial course. We believe, moreover, that the mechanical system of the committee of council on education, must tend seriously to the injury of the general taste of the nation, and to the consequent jeopardy of the progress of the higher branches of art. At present the nation is uninstructed in art—it is now going to be perverted—and what hope can there be for the development of taste and genius in the mechanical nation, which it is the effect of this system of model drawing to produce? We say, therefore, that on every ground it is well worthy of consideration whether we are to quit the natural method for one not possessing any adequate advantages to compensate for its striking defects. The training of the eye of the pupil, in the first instance, is everything—that is well known—and all that we want is that it shall not have a false bias. To go the full length of recommending at once the study of the living human figure we do not, but we must say, that if an objection exists to the human figure, on the plea of complexity, there are abundance of simple natural objects of still life, particularly in the vegetable kingdom, affording unobjectionable examples. Why the study of a leaf or of a fruit should be less capable of affording correct instruction to the eye than a circle or a square we cannot understand: and sure we are that more interest would attach to the natural object than to the wire or cardboard model. Indeed, Mr. Williams is obliged to confess to the power which natural objects have on the uncultivated mind, though he qualifies his admission by deprecating the greater love of the lower classes for luxuriance than for simplicity of form. We consider the system of model drawing as unjustified by reason and experience; and we think it was at least the duty of the government, with the ample means at their disposal, to have tried sufficient experiments on the comparative merits of the several systems of instruction in design. The system, now adopted, we are strongly of opinion, will turn out like that at the School of Design, productive of great mischief, and characterised as a serious blunder, happy if, as in the case of the School of Design, it be remedied in time.

On Mr. William's book we could have said a good deal, but we have thought it our duty at this length to enter our protest against the mischiefs likely to result from the adoption of the system he propounds, and to which we hope the attention of all who desire the sound progress of art, and the proper education of their countrymen will be directed. In parting, we beg to have it understood that our objection does not extend to the proper application of the system of model drawing, but only to its adoption as the means of teaching design in the first instance. We think that at a subsequent period, as a simple means of teaching practical geometry and the elements of perspective, that it is calculated to be highly useful; but it is to the preliminary use we object, as calculated to blunt the mind, instead of to strengthen it, and with such feeling we call the earnest attention of our readers to it.

Now that we possess the advantage of two competent commissions on national art, namely—the Commissioners of Fine Arts, and the Council of the School of Design, we think it is incumbent on the government to obtain their opinion, before further progress is made with the new system.

Arts, Antiquities and Chronology of Ancient Egypt. By George H. Wathen, Architect. London: Longmans, 1843.

Egypt is a theme so much wrought upon as a staple for book-making, that we have little temptation to take up a new *rechauffée* of the same subject. Relations of discoveries we can read with pleasure, or any masterly attempt to solve the mystery of its ancient history, but Mr. Wathen's book gave little promise from its announcement, and bears little fruit on its perusal. An architect may do much in Egypt for the information of the archeologist and professional man here, and Mr. Wathen, we believe, has ability enough, but instead of giving us any great account of what he saw, the book is a medley formed from the labours of others. First we have a miscellaneous preliminary chapter showing the common relationship of the priests of Memphis, the knights templars, heralds and freemasons, with a considerable portion of the apocryphal MS. purporting to be a conversation between Henry VI. and some freemasons, upon which, as Mr. Wathen has brought it in *à propos* of Egypt, we shall remark that it is a very extraordinary thing that curiosity should have been dormant as to the proceedings of the freemasons from the time of Henry VI. until the end of the 17th century, and that the regal MS. should be brought to light and transmitted for the examination of Locke, in the time of Christopher Wren. *Verbum sat.* The language of this document favours very much the suspicion of forgery, and the legend is so suggestive of doubts, that it would be safest to put it down to the account of some Chatterton of the 17th century, who have never been wanting at any day. That Locke was at all deceived by it is not wonderful, Chatterton and Ireland deceived better antiquaries. The masonic MS. immediately precedes a long article on the chronology of ancient Egypt, in which confusion is worse confounded, and although we have some glimmering that Mr. Wathen is occasionally right in the new views he propounds, he shows himself so illqualified for a guide, that we do not like to trust to his leading. We certainly wish he had left the subject alone. The next section of his book treats of the arts and antiquities of Egypt, and contains full accounts of the principal buildings and monuments, but chiefly derived from other sources. We regret this, as Mr. Wathen shows a power of observation, which might have been usefully employed in preparing a book of his own. This section contains, in defiance of order, a kind of journal of Mr. Wathen's tour in Egypt, which presents many points of interest, and is the only part of the book which he ought to have published. If we thought it worth while to exercise ourselves upon our author's antiquarian dissertations, we could do so to the satisfactory disproof of many of his positions, though not perhaps much to the gratification of our readers. As a specimen how little light the author is qualified to shed upon Egyptian lore, we refer to pages 56 and 176, 226 and 230 of his book. While, however, we thus object to his having put into his book what he could better have supplied with the results of his own observations, we are bound to admit that for those who desire information on Egypt in a compendious form, and particularly as relates to its architecture, a better book than Mr. Wathen's can scarcely be chosen. We extract from his pages the account of Karnak.

Next to the Pyramids the most wonderful relic of Egyptian art is undoubtedly the great Hall of the temple-palace of Karnak. From the inscriptions we learn that it was founded by Menepthah-Osiri I., father of the great Ramses, who was on the throne about the middle of the 15th century B. C. Its superficial area, 341 feet by 164, is sufficiently spacious for a large quadrangle. Majestic in ruin, what must it have been perfect! The massive stone roof is supported by a phalanx of 134 giant columns, ranged in 16 rows. Most of these are 9 feet in diameter and nearly 43 feet high; but those of the central avenue are not less than 11 ft. 6 in. in diameter and 72 ft. high; the diameter of their capitals at their widest spread is 22 ft. The walls, columns, architraves, ceilings—every surface exposed to the eye is overspread with intaglio sculptures—gods, heroes, and hieroglyphics, painted in once vivid colours. It is easy to detail the dimensions of this building, but no description can convey an idea of its sublime effect. What massive grandeur in its vistas of enormous columns! What scenic effects in the gradations of the chiaroscuro and the gleamings of accidental lights athwart the aisles! As you move on, new combinations unfold themselves every moment. Wherever the eye wanders it is filled with picture—rank behind rank, vista beyond vista. Here your eye runs along a pillared avenue and rests upon a vast column at the end, torn from its basis and thrown against the next—now it "is led a wanton chase" through a labyrinth of columns, which from another point fall into regular succession.

The roof is formed of ponderous blocks stretching across the aisles. The three central avenues rise above the general level like the nave of a Gothic cathedral, and the spaces between the upper piers are filled with close-set loopholes. Besides these, the only openings for light appear to have been the great doorways at the ends of the middle avenue and a few slits in the roof of the remote aisles. Thus while a solemn gloom reigned through the interior generally—so grateful to the eye in this land of glare and glitter—the nave was strongly lighted and brought into prominence as a master line bisecting the hall; and a fine gradation of shade, passing off thence into the obscurity of the distant aisles, heightened the effect of the perspectives.

All the resources of Egyptian architecture are here displayed in perfection;—its enormous masses, its long, close files of columns, its deep seclusions, and its rich pervading sculptural decoration. Burke could not have wished for a happier illustration of that part of his theory which refers the sublime in architecture to *succession* and *massiveness*.

The demolition of some of these masses excites even more wonder than their erection. Solid pylons of enormous bulk are broken up or riven in twain. Vast *built* columns seem to have been dragged from their foundations *en masse*. Architraves many tons in weight, wrenched from their place, now impend over the aisles, suspended by yet heavier masses which have perhaps been thus nicely poising them for ages. One might believe they were giants in those days,

"Giants of mighty bone and bold emprise!"

But the Hall of Columns was but a part of this wonderful fabric. Immense pylons, half buried quadrangles and halls, granite obelisks, and tremendous piles of fallen masonry once formed a range of buildings upwards of 1200 feet in length. The chief entrance was through the gateway of the west front, 63 feet high. Besides these there were other isolated and subordinate buildings. The whole appear to have been separated from the din of the city by an outer peribolus of unburnt brick, inclosing an area about 580 yards in length. A succession of four great propyla led across this area to the side of the chief structure. The outermost, as it was exposed to the view of the city and first received the advancing procession, was the most magnificent. Its length or base line is about 225 feet, its solid width 40 feet; the central gateway is of the granite of Syene. * *

An avenue of colossal sphinxes appears to have been continued from Luqsor up to the outer precinct of Karnak. The few that now remain are mutilated and half interred: but how imposing the effect of such a vista extending nearly a mile and a half over the plain terminated by the great façade of Luqsor! How exactly adapted for the pageantry of processions!

The illustrations, often from the drawings of the author, are of much interest, and we cannot but regret that he has not used his pencil more than his pen.

On the Laying out, Planting, and Managing of Cemeteries, with fifty Engravings. By J. C. Loudon. London: Longmans, 1843.

The establishment of Cemeteries throughout the country, must be gratifying to all who take an interest in public decency and public health, while they possess the extrinsic advantage of affording greater scope to art, and contributing to the healthful exercise of the people. The churchyard is an opprobrium in a civilised community, neither harmonizing with the respect due to the dead, or to the care requisite for the living, and the appropriation of eligible places of interment, is a great step towards a better system. Few of our large towns are now without their cemetry, or city of the dead, and the metropolis has the advantage of being girt with many picturesque and interesting establishments of this kind. Starting from Earl's Court, the circle is continued by Kensal Green, Highgate, Abney Park, the Tower Hamlets, Nunhead, and Norwood, each possessing its peculiar beauties and forming an embellishment to the metropolis, of which several of them enjoy views not to be equalled in the world for grandeur or interest. What more fitting abode for the dead, than looking down on the wide-spreading city in which their lives were passed; hovering, as it were, over the scene in which their loved descendants move, and awaiting their presence. How much better is this than the Hades of an Egyptian tomb! With the extension of cemetries, attention has been called to the principles on which they are to be founded, and it has fortunately induced Mr. Loudon to take up the subject. Those who know his accuracy, his minuteness, and his completeness, will be prepared to acknowledge the merit of the present work, which, without wandering into idle and useless details, treats the subject comprehensively, so as to afford every information which is essentially requisite with regard to it. While attending to the professional usefulness of his work. Mr. Loudon, with his usual good feeling, has not failed to call attention to the necessity of any improvements in the mode of interment. He urges most strongly the necessity of no corpse being interred with less than six feet of earth over it, and supports it on every ground of propriety and necessity. He suggests also several improvements as to the mode of laying out cemetries, and remodelling churchyards, and in fine, the reader will peruse his work with interest and instruction.

Ancient Irish Pavement Tiles; with Introductory Remarks. By Thomas Oldham, A.B., F.G.S. Dublin: Robertson.

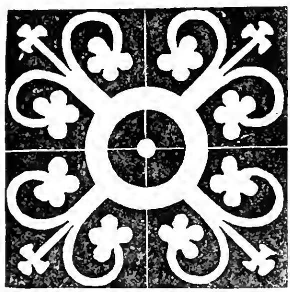
This work is of the same value with regard to Irish examples of encaustic tiles, as Mr. Bowyer Nichols' is as to those of England, and shows a laudable desire on the part of the sister country, to draw profit from her antiquarian relics.

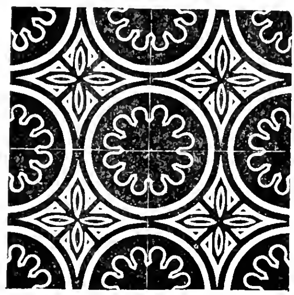
The Irish specimens of tile are of three distinct kinds. First, impressed tiles; second, encaustic tiles; and third, tiles in relief. Of the first class, Mr. Oldham states, that the Irish specimens are principally of the ordinary red colour of the clay, the surface being coated with an opaque varnish or glaze, generally of a greenish yellow colour, but occasionally of a dark purplish black, and extending equally over the indented pattern. Although similar examples have been found occasionally in England, in which the hollows were filled with a different substance, removeable by washing, our author observes, that he has seen no such case in Ireland, and thinks it exceedingly improbable that such ever was the case in Irish tiles. In the encaustic variety, the surface is quite smooth and flat, the pattern being produced by a differently coloured substance inlaid. The colours are generally bright red and yellow, or purplish black and pearl grey, and sometimes of purplish black and deep red. The third variety has the pattern formed in low relief. To this latter variety Mr. Oldham assigns the later date, considering it referable to the Tudor times; some of the other examples are however as old as the middle of the twelfth century.

Mr. Oldham mentions some curious facts with regard to the Irish tiles. He says, the identity with English specimens is often recognizable. Thus several of the patterns now remaining at St. Patrick's, Dublin, are nearly identical with some from Malvern, in Worcestershire, and it is of additional interest to find, that about the probable date of these tiles, a connection existed between the two places, for in 1225, the year in which St. Patrick's was made a cathedral, the prior and brethren of Malvern the Less, re-granted to it one half of the tithes of Castleknock, which had been given them in 1221. A kiln, it appears, has been discovered at Malvern, with portions of tiles in the several stages of the progress, and the tiles there used were manufactured on the spot; whence Mr. Oldham conjectures, that some of the Irish tiles were also derived from the same source. The water communication by the Severn and Bristol with Ireland, would favour this idea. Notwithstanding occasional importations, our author is however of opinion that the majority of the Irish tiles were made on the spot.

The following anecdote with regard to the early use of ornamental tiles, is entertaining. The author says:—

But if, on the other hand, our supposition that the pavement tiles at Mellifont were laid down at the time of its erection, (1142—1157) by monks from Normandy, be correct, it would then appear more probable, that the first knowledge of these tiles was derived from thence; and bearing in mind that Mellifont and Bective were both Cistertian establishments; the following notice, obligingly communicated to us by the Rev. Richard Butler, is extremely interesting. In Martini's Thesaurus Anecdotorum, among the "Select statutes of a general chapter of the Cistertian order" is one—"Anno 1210. Let the Abbat of Beaubec (in Normandy) who has for a *long time* allowed his monk to construct, for persons, who do not belong to the order, pavements, which exhibit levity and curiosity, be in slight penance for three days, the last of them on bread and water; and let the monk be recalled before the feast of All Saints, and never again be lent, excepting to persons of our order, with whom, let him not presumeto construct pavements, which do not extend the dignity of the order." These pavements must have been





either mosaics, (tesselated pavements) or tiles; probably, from the manner in which they are described, the latter. In either case, it proves that ornamental pavements had been a long time in use prior to the beginning of the thirteenth century. Nor should the fact be overlooked of the jealousy with which the use of them was sought to be confined to this monastic order.

Of some of the tiles, by the kindness of the author, we are able to give specimens, and we beg to observe, that the work is a valuable contribution to our knowledge of that branch of art.

The Student's Guide to the Practice of Measuring and Valuing Artificer's Work. By a late Eminent Surveyor. London: John Weale, 1843.

To the student this will be found a very useful guide, as far as it goes, but it is not sufficiently extended to be of that benefit the title led us to expect. It does not explain in what manner the student is to set about measuring or estimating a building, in commencing and proceeding from the foundation to the top in brickwork, and from the roof downwards to the lowest floor in carpentry, or the method of proceeding on each floor in the joining, first with the floor, then the skirting, windows, doors, &c.; nor in the plasterer's work commencing with the ceiling, then the cornice, partitions and walls: we have just given this slight and hurried sketch to show that there is a system adopted by all surveyors of any practice in measuring a building, and without such a system, the tyro will get himself into a labyrinth of difficulties, and probably omit some important part of the works. We may probably at a future opportunity be induced to give some instructions on measuring, for we have often seen attempts to lay down rules for that purpose, but none of them appear to us to be of that satisfactory character which we think suitable to the student—however, the work now before us, for the present we recommend, as we consider it the best that has hitherto been published, and will render some assistance in valuing and making out builders work, and give some insight into the abbreviations, method of entering the measurement, the abstract and drawing out the bill of quantities.

A course of Practical Geometry for Mechanics, by W. Pease.—This book contains the principles of Geometry, which the author has condensed very satisfactorily into a small space, so as to render the work both cheap and useful to the student.

The Guide to Hayling Island near Havant, Hants.—To the visitors of this watering place this guide will be useful.

PROPOSED EXTENSIVE IMPROVEMENTS IN THE CITY OF LONDON.

At the last Court of Common Council, the Special Committee appointed to report upon the proposed improvements in the city, presented their report, which certainly contains numerous suggestions, but we fear it will be several years before they can be carried into effect; they observe that:

It has long been the subject of public complaint, that Newgate-street, Snowhill, and Holborn, the great thoroughfare to the north-western, and that of St. Paul's Churchyard, Ludgate-hill, and Fleet-street, to the western part of the metropolis, are both quite inadequate to the immense traffic of carriages, wagons, and vehicles of every description which throng in those directions: and the numbers of wagons and carts which convey provisions to and from Newgate-market frequently choke that thoroughfare, creating delays and inconvenience to the mail-coaches, and other impediments to the Post-office arrangements. The special committee having examined carefully those plans which have been suggested to the Commissioners of Woods and Forests for a new thoroughfare, commencing in the neighbourhood of Leicester-square, through Lincoln's-inn-fields into the city, crossing Farringdon-street by a viaduct, next considered the practicability of forming a street which would connect the end of Cheapside with such a thoroughfare at Lincoln's-inn and with a branch diverging into Holborn, which would effectually relieve the great pressure of the public traffic in the thoroughfares alluded to, and at the same time render a viaduct at Holborn-bridge unnecessary. They were of opinion that the formation of a street combining these desirable objects was decidedly practicable, the street to commence at the east end, and continue along Paternoster-row, through Amen-corner, across Farringdon-street to the south-west corner of Farringdon-market in a straight line, the main line to continue across the middle of Fetter-lane to the city boundary, and a branch to diverge from the corner of the market to the end of Fetter-lane, at the summit of the hill in the wide part of Holborn. The special committee having had the levels in this proposed new line accurately taken, find that the greatest inclination of any part of it would not be more than about 3 feet in 100, and that only for the distance of 370 feet. It occurred to them in pursuing the investigation, that this new line would be still greater improved by the removal of the whole of the houses between the north side of St. Paul's Churchyard and Paternoster-row, from the end of Cheapside as far as Ave Maria-lane, which could be done for the additional sum of £150,000. Should this be effected, that magnificent structure would terminate a vista of upwards of one-third of a mile, and the whole would, in addition to the increased facility and convenience which would be afforded to the growing commercial traffic of the city, form one of the grandest improvements of an architectural character, yet achieved in the metropolis.

The order in which the special committee have classed the improvements which they consider called for, is according to the relative importance of each, and as follows:—

A. From the east end of Paternoster-row to Fetter-lane, and a branch street to Holborn, commencing with the houses at the west end of Cheapside, projecting beyond the line of St. Martin's-le-Grand, all between Paternoster-row, St. Paul's Churchyard, as far as Ave Maria-lane, Amen Corner, crossing the Old Bailey, to Farringdon-street, to Shoe-lane, Printer-street, Great New-street, to Fetter-lane to the city boundary; and the branch street from Little New-street, to the north end of Fetter-lane, Holborn, about 3360 feet in length. The great st acclivity in the whole of this line will not be more than 1 in 31, and that for only about 370 feet.

B. From the north end of Dowgate-hill to the east end of St. Paul's Churchyard, thence to Earl-street, Blackfriars, through Tower Royal, Little and Great Distaff-lane, crossing the Old Change into St. Paul's Churchyard, about 1360 feet in length, and from the Old Change, through Knight-rider-court, Carter-lane, Godliman-street, Bell-yard, Addle-hill, to the east end of Earl-street, about 1200 feet in length.

C. Watling-street, from Aldermary Church to the west end of St. Paul's Churchyard, about 1055 feet in length.

D. The Poultry, on the north side, to the Old Jewry, and 100 feet of the north side of Mansion-house-street, about 1055 feet in length; from the Mansion-house across Bucklersbury and Size-lane to Queen-street, from Watling-street to the east end of Basing-lane, the east side of Queen-street from Watling-street to Thames-street, about 1400 feet in length.

E. Lime-street, east side, from Cullum-street to Fenchurch-street, Leadenhall-market from Fenchurch-street through to the south end of Gracechurch-street, about 800 feet in length; Aldgate, south side, from the Saracen's Head to Jewry-street, and the east end of Leadenhall-street at its junction with Fenchurch-street.

F. Broad-street buildings to the Curtain-road, through Halfmoon-street to Sun-street, thence to Skinner-street, and on to Worship-street, about 1550 feet in length.

G. From Aldersgate-street, opposite the end of Jewin-street to Smithfield, and from the corner of Little Britain across Bartholomew-close, to communicate with the above line of street to Smithfield, about 1280 feet in length.

H. Threadneedle-street, north side, at its junction with Broad-street, and south side, from the church of St. Benet Fink, to Finch-lane, about 265 feet in length.

I. Holborn-bridge, north side, about 90 feet in length. Butcherhall-lane, east side, about 85 feet in length. St. Martin's-le-Grand, north-east corner, Angel-street.

K. Maiden-lane, north and south sides, about 275 feet in length; Jewin-street, south side from the corner; Redcross-street to Redcross-square, and north corner next Aldersgate-street; Aldermanbury, the west side of the south end; Milk-street, east side next Cheapside; White Rose-court, Coleman-street, and Mason's-alley, Moor-lane, south side, east corner, and north end, west side, from White-street to Type-street, and south end, Milton-street, east side; New Bridge-street, Blackfriars, through Tudor-street to the Temple.

"Having thus detailed these improvements, the special committee turned their attention to that part of the reference whereby we were directed to report our opinion as to the best means of accomplishing these objects, and having had under consideration the various improvements which have been carried out during the last 12 years, as connected with the avenues and approaches to London-bridge, ascertained that our expenditure in this respect has averaged about £150,000 per annum; a sum which they apprehended, if the same could be provided for a few years, would enable all the proposed improvements to be carried into effect; and feeling that the corporation have not the means at their disposal of effecting these improvements, however desirable the same may appear to be, the special committee were of opinion, as Her Majesty has been graciously pleased to appoint a special commission for the purpose of considering of further metropolitan improvements, which commission is now sitting, that a favourable opportunity exists for drawing the attention of the Government and the commission as to the best means to be adopted for raising the requisite funds for these purposes, and recommended that we should be empowered to confer with them upon this desirable object; and we agreeing with the special committee in the said report, submit the same to the hon. court."

The report was signed by 21 members.

THE TWEEDDALE PATENT DRAIN TILE AND BRICK MACHINE.

Fig. 1. Tile Machine.

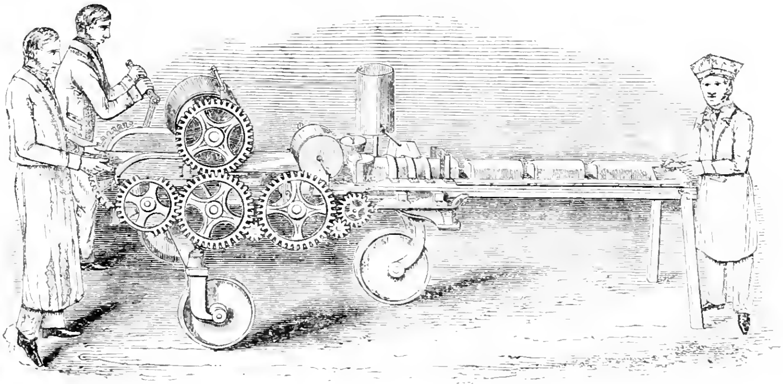


Fig. 2. Brick Machine.

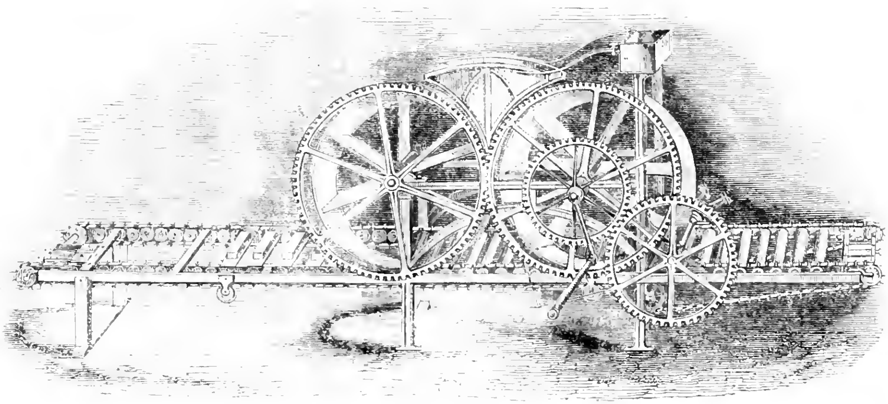

These machines, the invention of the Marquis of Tweeddale, have recently undergone very considerable improvements, and are now made to be worked by manual power, and are so portable that they may be removed and placed in any part of the tile sheds or brick fields. Formerly the machines were worked only by steam power, which in many cases was found to be highly inconvenient and expensive, as it was necessary to have the machines fixed and the clay brought to them sometimes at a considerable distance. The new machines, exhibited in the above engravings, can be worked by one labourer independently of the filler and attendants to remove the bricks as they are made.

The machines act with great simplicity, yet with the utmost accuracy. The one used for tile making, Fig. 1, consists mainly of two iron cylinders, over which webs or bands of moleskin, or other suitable cloth, are made to pass. By this arrangement the clay is pressed into a web of uniform thickness, without adhering to the cylinders. It is then carried over a covered wheel, slightly curved on the rim, and begins to assume the bent shape of a draining tile; a tendency which is increased by several inexpensive but effectual contrivances; and the tiles are polished and finished by passing through three graduated iron moulds of horse-shoe form, as seen in the centre of the machine, being at the same time moistened from a cistern on the top of the machine. The tiles are then cut off, with mathematical accuracy, to such length as may be required (fifteen inches being generally recommended as the most profitable and convenient), and then they are conveyed to any requisite distance by an endless web, and from thence are placed by two lads on the drying shelves. Flat tiles, or soles, are formed in precisely the same manner; except that they are partially divided into two portions while passing through the moulds, the quantity of clay required for one draining tile being the same as for two soles. The tile machine will make from 10 to 15 bricks per minute.

The brick machine, Fig. 2, is on the same principle, but varied to suit the different character of the article required. The clay is placed in a receiver or "hopper" above the two cylinders; and it descends between them into a mould or box, in such a way as to become perfectly formed and pressed into the shape of a brick in the transit. By a recent skilful improvement, a series of palate-boards is borne along by an endless iron chain; and the adjustment is so correct that at the exact moment of passing under the mould, each board is lifted to receive the new formed brick as it is emitted from the mould, and separated from the main body of clay; the palate board then drops again into its place with the brick, and is conveyed horizontally along the web just mentioned; hence it is removed on to barrows by the barrowmen.

It is not the least of the merits of both machines that, although acting with the accuracy of clockwork, they are not liable to derangement; and that, while they are suitable for the application of steam or other power when very large quantities are required, yet they are so simplified as to be also within the management of a couple of common labourers, with the assistance of two or three boys to remove tiles, or the like number of men in the case of bricks.

The quantity of articles produced is not limited by the machines, as they will manufacture any number that can be conveniently taken away. The general range is from 15 to 20 bricks or tiles per minute, when hand labour is employed to work the machines.

Several of these machines are now in operation in different parts of the United Kingdom, and on the Continent. The principal portion of the bricks for the rebuilding of that portion of Hamburgh destroyed by fire, are, we are informed, made by these machines. One of the machines may be seen at the Company's wharf, Millbank, Westminster, near Vauxhall Bridge.

THE XANTHIAN MARBLES IN THE BRITISH MUSEUM.

Amongst the valuable, though to the public taste not the most attractive, additions to the contents of the British Museum, are the marbles brought from Lycia, and which have been placed temporarily in the two rooms leading to the Elgin marbles. These treasures not being as yet entered in the synopsis, or presenting to an ordinary observer no striking or remarkable feature, have not yet attracted that notice which their importance demands. Still they have not been altogether unnoticed by the crowds of holyday folk who have thronged to the Museum during the last few days, and who seem unanimously to regard them as "very ancient" and "very curious."

These marbles, which were discovered by Mr. Fellowes, while travelling in Asia Minor, in 1838, are said to be the most remarkable and important accession received by any European museum for many years, and have been obtained and brought to England in consequence of the greatest enterprise and self-denial on the part of the gentleman by whom they were discovered, and in consequence of whose representations respecting them they have been lodged in the British Museum. The marbles already secured to the British nation are but a small portion of those that abound in the interesting country from which they have been brought; they are, however, very valuable, and some idea of their quantity may be obtained when we mention that they were brought to England in 78 large and heavy packages.

The Xanthian, or Fellowes marbles, as it has been proposed to have them called, illustrate the mythology, the modes of warfare, and a variety of interesting features in the manners and customs of the ancient inhabitants of Asia Minor, who were originally settlers from Crete.

As might be expected, these sculptures do not, as works of art, rank with the Elgin marbles, but they are highly interesting as illustrating the state of sculpture in a much earlier age. They are supposed to include some of the earliest efforts of Greek art which have come down to our times.

The principal objects in the collection are those which Mr. Fellowes describes as the *bas-reliefs* representing the legend of the daughters of King Pandarus being carried away by the harpies, which were around the high square monument, which was called the harpy tomb. The marbles belonging to this tomb are placed in the centre of the grand central saloon, arranged as they were before being taken down. Near them is placed a model of the tomb, which was supported by a shaft 17 feet high, and weighing 80 tons, standing on a plinth 6 feet high. The tomb itself was 3 feet 3 inches in height, surmounted by a cover which weighed from 15 to 20 tons. The central saloon also contains some very beautiful frieze work, representing in *bas-relief* a bear hunt: all the figures, the horses and horsemen, the dogs, and the unfortunate bear itself, are very spirited and bold, but not highly finished specimens of art. Some of the figures on the harpy tomb, and those placed on the under ledge of the same large framework, bear a considerable resemblance to the figures on the monuments of Egypt; we may mention particularly the gods seated on chairs, one smelling a lily, and another giving a helmet to a warrior. In the anti-room there are several very rich friezes. One represents a sacrifice; the fire is burning on the altar, and a number of persons are approaching with various offerings, both animal and vegetable, and in cases the offering may be readily distinguished. The siege of the walled town forms in itself an interesting subject; the walls are defended by warriors armed with stones, which are also the weapons in general use among all the combatants; on the walls are a number of females, whose countenances indicate great distress, as they well may, for the artist has introduced an escalade, which is sufficiently indicative of the danger of the inhabitants. The friezes and the pediments in this room contain some figures, which for vigour of design, if not for beauty of execution, may vie with the Elgin marbles. Mr. Fellowes, in his account of the transmission of these marbles to England, remarks that the frieze so accurately illustrates the description given by Herodotus of the capture of the early city, that he could almost fancy that the neighbouring historian had written his history from it, commemorating an event which happened about a century before his era. We understand that a room is to be prepared expressly to receive this valuable addition to the antique sculptures with which our great national collection is enriched.—*Times*.

DREDGING AND DREDGING-MACHINES.

Sir—As to working a machine a-head by the engine, although, as you remark in your foot note to my communication on this subject, in the last number, it is one of the most obvious applications of the engine power, yet it is not equally so under all circumstances. Where a machine is used to keep a harbour dock or navigation *clean*, the application is most obvious and advantageous, as the traverse of the machine may be quite uniform; but where the natural bottom has to be dredged out, the advantage is not so great. Indeed, in such a case, it is impossible to apply a *constant* power to the bow chain in trench cutting, (or the lateral chains in radius cutting,) else the machine would be broken by natural interruptions, such as stones and roots of trees occurring. But if the engine power be applied to a crab-winch, and the chain be brought with about three turns round the winding barrel, so as to give it just sufficient friction to drag the machine under the ordinary resistance to the buckets, and of course allowing the end of the chain to coil upon the deck, an intermittent motion may be had. If, however, a man attend to this crab-winch while the machine is at work, and on the given signal from the captain, throws a slack of chain on the winding barrel to cause it to slip, and so stop the advancement of the machine, this motion may be rendered quite as manageable as if performed entirely by manual labour. It would, of course, be an object to dispense with the attendance of a man at the crab-winch or with the winch also, and to wind the chain on a barrel at the engine, but then no friction straps or the like could produce such a motion as that given by the man letting the chain slip or lose hold entirely, as required. A fast and loose gearing would scarcely do, but, with friction cones, it would certainly approximate to a hand motion, sufficient for ordinary cutting.

In my communication last month, I did not say what motive power I would apply to the lateral chains therein proposed, but the above remarks apply equally to them as to a bow chain. Where the motion of the machine (*i. e.* the progressive motion of the machine or boat to the stuff) may be uniform, the application of engine power would be an additional saving, as they would only require an occasional inspection, but in the case where the motion must be intermitted, the method of "radius cutting" reduces the labour of winding so much, that if a man attend to the chains he can also wind them. In a small machine, about 50 feet long, one lateral chain on each side may be sufficient.

As the reduction of the number of hands required to work dredging machines must be an object with every engineer whose works require the use of them, in as much as it is creditable to raise the stuff at the least expense which local and other circumstances will permit, many ingenious arrangements might be thought of. In those machines in which the bucket ladder is placed in the centre of the boat, there are levers at hand, by which the captain, while taking the soundings in the well, can raise and lower the ladder. In the same manner, when engine power is applied to the crab winchs, rods might be brought from their fast and loose motions, so as all to be at one point. Always adapting the machine to the nature of its work, I am not aware of any works where the machines are divided and adapted to different sorts of work, which has made me keep this point in view in my preceding remarks.

If each machine be adapted both for light and heavy work, there must be a waste of power; but more on this again.

W. C., C. E.

30, *Hope Street, Glasgow*,
26th April, 1843.

Paris.—The monster elephant which has for 30 years guarded the Plac de la Bastile, in memory of Napoleon's Egyptian exploits, is about to be cast in bronze, for the decoration of a grand fountain to be erected in the Place du Trône. The giant animal is already caged, for the purpose, within a system of boardings forming a vast workshop, and at once exciting and baffling the curiosity of the Parisian street hunters. The papers also state, that the commission for erecting the tomb of the Emperor Napoleon has come to a decision that the baldachin of the altar at the Invalides, with its gilded columns, shall be suppressed; that the equestrian statue of the Emperor shall be erected on the Esplanade, and not in the Cour Royale, as designed by the architect, and that the figure of the Emperor shall be in his historical dress, and not in the Roman costume. The Minister of the Interior has given commissions for twelve statues, to be placed in the niches of the principal façade of the new buildings at the Hôtel de Ville. The following are the subjects:—Frochot, Voyer d'Argenson, Etienne Robert, Vincent de Paule, L'Abbé de l'Epée, Robin, Jean Aubry, Hardouin-Mansard, Guillaume Budé, Mathieu Molé, Michel Lallier, and La Vacquerie.

C. W. WILLIAMS' ARGAND FURNACE.

Questions relative to the effect of C. W. Williams' Argand Furnace, as answered by the Commanders and Engineers of the undermentioned Steamers, 28th March, 1843.

Names of Steamers.	*How long since the apparatus was introduced into your Vessel.*	*Did your furnaces make much smoke before they were altered?*	*Do they make less smoke since they were altered?*	*Had you a sufficient supply of steam before the furnaces were altered.*	*Have you as good or better command of steam since the alteration?*	*Does the use of this Apparatus effect any saving of fuel, and to what extent?*
Hibernia.	12 months.	A great deal of smoke.	Much less smoke, scarcely any to be perceived.	Yes — but not too much.	Yes—a great deal better, and was enabled to blow off copiously.	On the average of trips we save at least 3 cwt. per hour.
Ballinasloe.	7 months.	Not much smoke.	Since the alteration there is less smoke than before.	Yes.	I should say a better command of steam, though we have *new cylinders of larger dimensions.*	Consumption much about the same as before, notwithstanding about 16 horses power added, and an increase of two revolutions.
Nottingham.	19th April, 1841—say two years.	Yes — a very thick black smoke.	No smoke is now made except when fires are first lighted, or coals are being thrown on.	No — scarcely enough of steam.	We have now an abundant supply of steam.	Consumption of fuel the same as before.
Athlone.	7 months.	A great quantity of smoke was made previously.	No smoke is now made after the fires are put in good order — a light smoke when men are firing.	Rather insufficient in steam.	We have now a very plentiful supply of steam.	About four tons of fuel less is now consumed in the trip than before the alteration.
Royal Adelaide.	10 months.	Yes—we smoked very much.	Only when fires are first lighted, or with bad coal.	No—we had but little except with very good coal — then with great exertion we worked to full power.	We are convinced we have, and particularly with good coals.	Yes — this is experienced when burning good coals, but not when with a bad quality.
Royal William.	Nov. 23, 1843	Made much smoke with the former boilers.	Very little smoke now.	The apparatus attached when the present boilers were put in.	Sufficient supply of steam.	Apparatus always applied to these boilers.
Prince.	Always to these boilers.	Smoked much with former boilers.	We have made very little smoke since the commencement, with present boilers.	Apparatus always attached to present boilers: plenty of steam at all times.	Apparatus always attached—plenty of steam at all times.	Apparatus always attached, therefore cannot say.
Princess.	9 months	A great quantity of dense black smoke.	They now make scarcely any smoke after the fires are well lighted.	We had sufficient before the alteration.	We have quite sufficient, as we had before.	Without the air pipes we made 16 voyages .. 371 hrs. Coals consumed 571 tons With the air pipes we made 16 voyages .. 379 hrs. Coals consumed 522 tons Saving .. .. 49 tons
Leeds.	Above 2 years	Going before the wind they smoked considerably—at other times not so much.	No smoke except when firing up or making the fires, and then only a short time.	We always had a good command of steam	We have better command of steam; if the coals are good, we can make any quantity of steam with the greatest ease.	To the best of our judgment, about 4 cwt. per hour.
Birmingham.	1 month.	At times they smoked.	No black smoke now appears while under way, but sometimes a little gray colour a few seconds after firing.	I have always a sufficient supply of steam.	At all times a sufficient command, and are now enabled constantly to blow off steam.	We save about 1 cwt. to $1\frac{1}{2}$ cwt. per hour.
Mars.	9 months.	A dense black smoke.	Much less smoke.	No, we had not sufficient steam.	Very much better.	From the nature of our service I cannot say.
Oriental. (*From Alexandria*)	20 months.	Yes—we smoked considerably, as much as any vessel of our class.	After all is warmed through we do not smoke, only when firing up or raking, and then only a slight volume for a few seconds.	We were always pretty well for steam when using good coals.	We consider that we have a much better supply with the air apparatus—there is no question of it.	We think we are saving from three to four cwt. per hour. For many voyages our consumption averaged 26 cwt. per hour. It was 30 cwt. previously.
Hindostan. (*From Calcutta.*)	Put in on arrival at Southampton	Voyage from Liverpool to Southampton, smoked much, from both funnels.	Smoke is now seldom or never seen.	Not over abundant	Sufficient steam now.	The air boxes are a great saving, both in fuel and supporting the bridges.
Shannon. (*Glasgow.*)	4 months.	A great quantity of smoke.	Smoke nearly done away with, except at firing, and when raising steam from cold water.	Sufficient.	Much about the same.	From 15 to 20 per cent. of fuel is saved.
Dædalus. (*Liverpool.*)	9 months.	A great deal of smoke.	No smoke now except when the fire is lighted.	Not half enough.	Much better.	Yes, at least one-third.

Since the above was printed, the *Queen Victoria* (in Liverpool) and the *Brando* (in Glasgow) have been added to the list, in both of which the apparatus has been successfully applied.

C. W. WILLIAMS' PATENT SMOKELESS ARGAND FURNACE.

Sir—As the application of Mr. C. W. Williams' Argand Furnace to marine boilers has been questioned, we beg to request your giving room to the accompanying tabular view of its adoption on board several steamers, and to add that the apparatus continues to be applied to such boilers as from their construction are susceptible of improvement.

I am, Sir,
May 5, 1843. Your's obediently,
Dircks & Co.

P.S. By the returns in the foregoing table it will be seen that the advantages are greater in some vessels than in others. This difference is chiefly attributable to the construction of their boilers. In marine as well as land engine boilers, the arrangement of the flues frequently renders them incapable of improvement: such arrangement not only injuring the draught, but tending to obstruct, rather than aid, the natural and chemical process of the combustion of the gaseous matter of the coal. In some of the boilers in the above table, there appears to be a considerable saving of fuel where there had been a sufficiency of steam. In others, the advantage of the apparatus is shown by obtaining a better supply of steam from the same quantity of fuel. In all, the great evil of smoke is avoided. Where furnaces are properly attended to, by having the bars kept *thickly* and *uniformly* covered with fuel, smoke will be prevented, and more heat generated. Any deviation from this, by having the fire bars too long—by improperly feeding the furnaces or allowing the fuel to burn in holes or irregularly—or by heaping the fresh coals in front, and allowing the back part of the bars to be uncovered or without the full supply of fuel, will be attended, either with the generation of *visible* smoke, or the escape of the gases unburnt, though *invisible*, with a loss of heat, and consequently a diminution of steam. It is here to be noted, that the absence of *visible black* smoke is no test of the combustion of the gases. What is called the "combustion of smoke" is not unfrequently the effect of the mismanagement of the fuel, by which its inflammable gases pass away in an *invisible* form. Smoke is the result of the imperfect process of combustion of the gases, and as the process cannot be twice performed in the same furnace, the "combustion of smoke" is hence a chemical absurdity. Dr. Ure, writing to Mr. Williams, says, "I quite agree with you in considering the *prevention of smoke* to be the true mode of curing the nuisance; for when the carbonaceous particles become deposited, it is impossible effectually to burn them, so as to destroy the smoke which they occasion, or rather constitute." Professor Brande says, "As to the quibble about *burning smoke*, it is, in other words, burning what is to be presumed has already been burned, and therefore cannot be burned twice over," &c. "I can see nothing that in the least invalidates your views respecting the *prevention of smoke*, by the combustion of that which would become smoke, *if you would let it*."

NOTES ON THE USE OF SUBLIMATE OF MERCURY AND SULPHATE OF ZINC, AS PREVENTIVES TO DECAY IN TIMBER.

Various attempts have been made by different individuals to render timber indestructible, both as regards fire and the hand of time, also to render timbers of inferior qualities equal in hardness to those of the best description; for the two latter purposes a solution of pyrolignite of iron and chloride of lime have been employed, and for the former, solutions of the sulphates of copper and iron. It has long been known that the saturation of skins of birds and anatomical preparations, in a solution of corrosive sublimate of mercury, tended to their preservation, and it was suggested by Sir H. Davy and also by Mr. Chapman, that the same solution was capable of preserving timber; but it was reserved for Mr. Kyan to bring the subject to bear in practice, who, as long ago as March 4, 1828, submitted some timbers to his new process, and the first examination of which took place in three years afterwards, and the second in July, 1833, five years afterwards. Since then the use of sublimate as a preventive of dry rot and decay has been termed Kyanizing, after Mr. Kyan, who, in 1832, took out letters patent "for a new mode of preserving certain vegetable substances from decay," and in the same year had some specimens of timber, prepared with the solution, tested in the fungus pits of Woolwich dockyard, which stood the trial satisfactorily. In 1835, the paling of Regent's Park, in London, was so prepared, and in the same year Sir Robert Smirke employed Kyanized timber in the erection of the Oxford and Cambridge Club, and Messrs. Grissell and Peto, the builders, erected tanks and purchased the use of the patent, and Mr. Samuel Beazley, the architect, reported, in Jan. 1831, favourably of the paling in the Regent's Park, which had been submitted to the process. The above authorities, I have no doubt, gave the system of Kyanizing an impetus of which it has not yet lost the beneficial effect. Above twenty railway companies used the patent for the preparation of the sleepers of railways, both for cross and continuous bearings; it was used on the viaducts of timber on the North Shields Railway, by Messrs. Green, and also by the Honourable Commission for the repair of the Menai Bridge. The Kyanizing system has been introduced into Holland, where the Commissioners of the Dutch government made a favourable report in May, 1838, and it has also been used for the Austrian railways. A company is now using the patent in England under the title of "The Anti-Dry-Rot Company."

An improvement on mere saturation was suggested and acted upon by Sir William Burnett, in Aug. 1836, and being favourably reported on by the Admiralty, a tank was erected at Portsmouth, being of wrought iron, 52 ft. long, and 6 ft. diameter, and another was erected by the Hull & Selby Railroad Company, 70 ft. long 6 ft. diameter. The Anti-Dry-Rot Company, under Kyan's patent, has also a 60 ft. tank and hydraulic apparatus, at their works, City Road Basin. The timber is piled inside these tanks with interstices, and the air is exhausted by a pump to a vacuum of 25½ in. of mercury, and the solution then admitted, and submitted to a pressure of 100 lb. by a force pump, by which means the saturated solution is forced into the pores of the wood. Some doubts have been expressed as to whether the proper effect is obtained by this mechanical process, the action being chemical, and time for saturation being required.

The report of the Committee appointed by the Lords of the Admiralty printed by order of the House of Commons, July 9, 1835, contains the following observations, founded upon some experiments made at Somerset House. The solution used for preparing the timber, contains 224 lb. of the corrosive sublimate to 1062 gallons of water, or about 1 lb. to 5 gallons, and the cost of the sublimate 3*s.* 7*d.* per lb., and that the solution diminishes in bulk and not in strength by use.

Professor Faraday delivered a lecture at the Royal Institution on dry rot, in Feb. 1833, Dr. Birkbeck at the Society of Arts, Dec. 9, 1834, and Robert Dickson, Esq., at the Institution of British Architects, April, 1837, and a pamphlet was published by J. C. Adlard on Kyan's process, all approving of the process, which show the prominence this subject has assumed within late years.

The following is the cost of Kyan's process as first promulgated in January, 1836:—

	s.
Licence per load of 50 cubic feet	5
1 lb. of corrosive sublimate to 10 gallons of solution ..	5
Labour to 1 load of timber, filling and emptying tank, and unloading	5
Risk and profit, 25 per cent.	5
Cost of a load of 50 feet ..	20*s.*

Deals require to lie in the tank three days, and an extra day for every inch in thickness.

The largest tanks for mere saturation that I have any account of, were erected for the Great Western Railway Company, at Bull's Bridge, near West Drayton, under the direction of the engineer to the Company. These tanks were 9 ft. deep, and of an oblong trough shape, the size at the top was 84 ft. by 19 ft., and at bottom 60 ft. by 12 ft. 8 in. The sides were of 4 in. plank, American pine, supported on sills 12 in. by 10 in., and upright framing 10 in. by 10 in., and with sloping diagonal braces, 8 in. by 8 in., of which framing there were 9 sets in the length of the tank. The whole was sunk into the ground nearly level with the surface, the uprights standing about 2 ft. above the sides, to which were attached transoms to keep down the timber in the solution. The tendency of the timber to float was so great, that notwithstanding the bearing was only 19 ft., and the transoms 15 in. by 12 in., they were cambered or bent upward nearly an inch and a half, and in one instance the whole tank was disturbed from its seat; the thickness of the sides being only 4 in. plank, the solution escaped, and ran into a ditch which communicated with a fish pond at a distance of about 600 yards from the tank; and notwithstanding the reduction in strength, the fish in the pond were killed.

The sublimate was dissolved in hot water, and added to the water in the tanks, the hydrometer being used to test its strength. At the end of the tank a mast was erected with a traversing boom, so as to be used as a derrick in filling or emptying the tank of timber. As a test whether the solution had penetrated to the centre of the timber, hydrosulphuret of ammonia was used, and if the solution had penetrated sufficiently into the prepared timber, being touched with the test a black stain would soon become apparent, although I must say I have not seen it act successfully when the timber was split far from the surface.

The preservation of timber from the dry rot is at the present moment attracting considerable attention, in consequence of Sir W. Burnett's process having superseded Mr. Kyan's in the good opinion of the authorities of the navy. The *United Service Journal* for April has an article on naval improvements in the 19th century; from the fourth notice on dry rot, is condensed the following account of Burnettizing. It appears that Sir W. Burnett, Physician General of the Navy, knowing that the precipitate caused by Kyanization was soluble in sea water, substituted water saturated with the chloride of zinc, with decided and beneficial effect; and "we trust," says the editor of the *Journal*, "the day is not far distant when not a load of timber or a bolt of canvas will be used in Her Majesty's service without being Burnettized." The principle of Burnettizing was reported upon by the Master of Woolwich Dockyard and his assistant, 15th July, and by the Admiralty, 26th July, 1841. Tanks are established at each of the dockyards, at Portsmouth, Plymouth and Chatham; that at Portsmouth is 6 ft. diameter, and 52 ft. long, and proved to a pressure of 200 lb. on the inch. In consequence of the successful results of all the experiments, Sir William was induced to take out a patent. In the above named Journal, amongst the correspondence, is a letter from the Liverpool Registry of Shipping stating that rock salt filled between the timbers of the frame of a ship, is a preventive or cure for dry rot, even after it has made its appearance. In the *Mining Journal*, March 18, 1843, from a letter by J. Murray we learn that he applied sulphate of iron and a partial vacuum, caused by steam injection, to assist the penetration of the solution, 10 years before Kyan's process; through the same channel, he also states that salts of copper will coagulate albumen as well as chloride of mercury. The tanks of the Hull and Selby Railway, previously noticed, are more fully described in Vol. 5, page 202 of the *Journal*, being an account of the meeting of the Institution of Civil Engineers, March 8, 1840, where it is stated that 50 out of 70 of the prepared sleepers, used at the West India Dock warehouses, after being down for five years, were rotten, they had been prepared by simple immersion or saturation; and it is also stated, that some tanks of the Anti-Dry-Rot Company, in which the solution was kept, had decayed, and that the action of corrosive sublimate would be prejudicial to the use of iron bolts in Kyanized sleepers.

In the application of Kyanizing to railways, Mr. Giles was the first to apply it on the Southampton Railway; and of its application to building, Sir Robert Smirke at the Temple in 1833, also at the Custom House, Bristol, the Oxford and Cambridge Club, and the British Museum; also by Mr. Wilkins, in the erection of the National Gallery, and by Mr. Barry, at the College of Surgeons, in 1834, and in the same year by Mr. Abraham, at the Westminster Bridewell; and it has been also employed at Ramsgate Harbour by Andrew Turnbull, C. E. The above enumeration of works, in addition to the attention bestowed at the meeting of the Institution of Civil Engineers, is, I think, evidence enough to show that Kyanizing has not been superseded in public estimation by Burnettizing without a fair trial of its merits. Both processes, I think, will fall into desuetude, not from any defect in principle or not answering the end in view, but from the first cost of the tanks, the delay in time, the vessel not being capacious enough, and the extra delay and expense in delivery and cartage of the materials from place to place, or from the tanks to the works where the materials are required. This, I know, that the Kyanizing has signally failed in taking root in the provinces, and I could specify at least ten places where it has been given up. With respect to a railway with two lines of road where it is used, the cost per mile will be as follows: where cross sleepers are employed, each sleeper contains from 2 to 2½ cubic feet, and costs from 12*d.* to 13*d.* each for Kyanizing, exclusive of cartage from the place of delivery to the Anti-Dry-Rot station, and from thence to the works where they are required for use. The cost of sleepers of Scotch fir is about 4*s.* each, and of larch 5*s.*; price, of course, is ruled by the locality, taking, however, the cost of Kyanizing and cartage at 1*s.* 6*d.* per sleeper, and a double way, and placing the sleepers 3 feet apart, (although recently they are placed only 2 feet 3 inches apart,) and there being 1760 yards in a mile, the total cost of Kyanizing will be £132 per mile, which on some of the long lines amount to the sum of £20,000, an amount which ought not to be too rashly entered on without due inquiry.

In conclusion, I beg to be allowed to state that I was engaged in the use of the Kyanizing when Messrs. Grissell and Peto employed it; also, in the erection of the tanks of the Great Western Railway Company, and in the superintendence of the process, when performed by local establishments, of the Anti-Dry-Rot Company. I state this, to show that my opinion is not rashly formed, when I say that Kyanizing is grown into disuse, and that probably Burnettizing will also share the same fate, perhaps, without having so long a trial. With the concluding remarks of the Lecturer on Engineering at King's College, as given in a late number of the *Journal*, I cordially agree, viz., "'tis use alone that sanctifies expense." Although this paper may not possess the merit of being thoroughly original, yet I think it may claim no lack of inquiry into the writings of previous inquirers as to the merits of this question of preventives to decay in timber. To yourself my thanks are especially due, for your liberality and condescension in noticing my previous efforts, as a correspondent to your valuable periodical, amongst the general notices, as being the results of labour, and as valuable communications, but more especially for the particular notice in Vol. 5, page 397, where my efforts are designated as "practical and of great utility." Your kindness has given my study and reading an object, which is to employ my leisure profitably in the advancement of knowledge, and becoming of practical utility to my fellow men.

St. Ann's, Newcastle-upon-Tyne. O. T.

NEW PROCESS FOR MANUFACTURING LIME, &c.

A Patent has been granted to WILLIAM EDWARD NEWTON, of Chancery Lane, for "*improvements in manufacturing lime, cement, artificial stone, and such other compositions, more particularly applicable to working under water, and in constructing buildings and other works, which are exposed to damp.*" (A communication.)—Sealed the 3rd of April, 1841.

This invention consists, Firstly—in the formation, by certain new processes, of an hydraulic lime and cement, which has the property of becoming hard and solid, when under water, or exposed in damp situations. Secondly—in the application of the same principles to the hardening of soft stones, for the purpose of making hard artificial stones. Thirdly—in the employment of the same process for hardening wood, and preserving iron from the effects of damp, &c.

The following is the principle upon which the invention is founded, and the methods employed for carrying it into effect: The property which certain sorts of lime possess, of being hydraulic, or hardening under water, is caused by a certain combination of the lime with silica, alumina, and sometimes also with oxide of manganese, and oxide of iron. The object then of this invention, is to facilitate the combination of the lime with those oxides, by means of agents not hitherto employed. Thus, in operating by the dry method, as is generally the case, instead of calcining the lime-stone or lime with sand and clay, the inventor, in order to facilitate the combination of the silica and alumina with the lime, introduces a small quantity of potash or soda, in the state of carbonate, sulphate, or chloride, or of any other salt of these bases, susceptible of decomposition, or becoming a silicate, when such calcination takes place. The salt of potash or soda, the quantity of which varies from three to six per cent. to the quantity of lime, is employed in the state of solution, so as to penetrate and mix better with the alkaline salt in the chalk or slacked lime. Calcination effects the rest, in the ordinary manner.

In order to combine or incorporate more equally, by the dry method, the alumina, and the oxides of manganese, and of iron, with the lime, the sulphates of these bases are first decomposed by the slacked lime, by making a paste with a solution of the sulphates, mixed with the lime. This paste, into which the sulphates in question enter, in the proportion of from six to ten per cent. of the lime, is then calcined, in order to produce an hydraulic lime. All sorts of lime are made hydraulic, by the humid method, by mixing slacked lime with solutions of alum or sulphates of alumina; but the best method consists in employing a solution of the silicates of potash, or of soda, called liquor of flints or soluble glass. An hydraulic cement may also be made, which will serve for the manufacture of architectural ornaments, by making a paste of pulverized chalk, and a solution of the silicate of potash, or of soda: in working with this plaster, it becomes much harder than ordinary plaster.

These same silicates of potash or soda, dissolved in water, will also harden chalk, or soft and porous stones, and transform them, artificially, into hard stones. In order to do this, these soft stones, either rough, or cut into their proper forms, must be soaked in a solution of the silicate, either warm or cold, and allowed to remain there a longer or shorter time, according to the degree of hardness which it may be necessary to give them; after which, they must be taken out and left exposed to the air. At the end of a few days, stones, thus prepared, will have acquired a hardness equal to that of marble; and this quality, in a little time, pervades the whole mass; for if, for the purpose of polishing, the outer coat or surface be removed, the inner one, which at first is not so hard, will harden in its turn, by exposure to the air. This takes place as far as the silicate has been able to penetrate. A more superficial hardness is obtained, by applying the solution of the silicate of potash or soda, by means of a brush. It is in this manner that walls, constructed of chalk and mortar, may be hardened. Sculpture, and various other objects, which may be made or prepared in chalk, may be hardened, and afterwards serve for decorating buildings, and other purposes, without the fear of their becoming injured by frost or damp. Chalk, hardened in this manner, may also be used as a substitute for the stones now employed by lithographers. Plaster models may also be hardened, by placing them, for some time, in a solution of the silicate; but it would be still better to add a portion of the solution to the paste, at the time of making the model, or using the plaster. The silicate of potash or soda is prepared by fusing one part of white siliceous matter with from one and a half to two parts of potash or soda, in the ordinary reverberatory furnaces, or in a glass-maker's or iron crucible. The solutions may be used of any density for plaster; but they should be weaker for chalk. In the last place, the inventor has found that the silicates of potash or soda, when dissolved in water, decompose spontaneously in the air, and cover the objects, to which their solution has been applied, with a strong covering or layer; therefore, by applying the solution of silicate of potash, or of soda, to polished iron, and allowing it to dry in the air, the metal is preserved from oxidation. By soaking wood many times in this solution, and allowing it to dry in the open air, every time after it has been placed therein, it becomes so much penetrated with silica, that it acquires a considerable density and degree of indestructibility.

The solution of the silicate of potash is not the only substance which, by being injected into porous bodies, tends to harden them. A mixture, made from a solution of bicarbonate of ammonia, and of chloride of magnesium, may be successfully employed; or a mixture of the solutions of ammonia and chloride of calcium may be used. In these latter cases, instead of having siliceous injections, they are either magnesia nor calcareous. Soft and porous stones may also be considerably hardened, and defended from the action of damp, by first well drying them, and then dipping or steeping them in sulphur, or some natural or artificial resinous or bituminous substance, rendered liquid by heat.

The patentee claims, Firstly—the application of certain new means, to change or convert all descriptions of lime into hydraulic limes and cements, or such as become hard under water, or when exposed in damp situations, by combining these limes and cements, with silica, alumina, the oxide of manganese, or the oxide of iron, either by the dry or humid method. Secondly—the manufacture of hard artificial stones from chalk, plaster, and all porous stones in general, by injecting into them, or imbuing them with silica, or the carbonates of magnesia or lime, by any of the above-described processes; or by causing them, by virtue of their porous nature, to absorb either melted sulphur, or bituminous, resinous, or fatty matters, properly liquified by means of heat. Thirdly—in the employment of the silicates of potash or soda, for making or forming a stony plaster or coating upon a variety of substances; thereby preventing iron from becoming rusty or oxidized, and rendering wood and other organic matters harder, and not liable to decay.—[*Inrolled in the Petty Bag Office, September*, 1841.]—*London Journal.*

INSTITUTION OF CIVIL ENGINEERS.

February 3.—The President in the Chair.—*(Continued.)*

The Thames Tunnel.—Sir M. Isambard Brunel presented a design intended to illustrate the mode of securing the poling-boards of the shield of the Thames tunnel. The poling-boards, shown in the drawing, he described as being intended to close the whole area of the excavation in the front, as the side and top staves were intended to secure the sides and top of it. The shield (weighing nearly 180 tons) in passing over the ground, served materially to compress it, and make a firmer foundation for the tunnel. When it was considered that the mass of ground removed weighed 63,000 tons, while the brick structure by which it was replaced weighed only 26,160 tons; some idea might be formed of the difficulties which had been encountered in the progress of this undertaking. It would be seen by reference to the early reports, that 540 feet of tunnel had been made in the course of sixteen months, viz., from the 1st of January 1826, to the 27th of April 1827. At that period the miners and bricklayers struck, without even securing their work. In this emergency, after standing still a week, new hands were engaged; the result was, that on the 11th and 12th of May, the ground showed symptoms of giving way, and on the 18th the river broke in and completely filled the tunnel; the length of brickwork then completed was about 550 feet. He was convinced that no irruption would have occurred but for the desertion of the men, for at no previous period had so much work been done; the average progress being 12 feet per week for sixteen weeks, and having at that time the advantage of his son's services and those of experienced assistants, the work might have continued, and the tunnel would have been finished in about four years. After this irruption, an advance of only 50 feet was made within the period of the year 1827, and in consequence of a second irruption, the work was totally abandoned. In the year 1835, after a lapse of seven years, being liberally assisted by the Government, a new shield was provided, and the work was resumed in the beginning of March 1836. The work, however, proceeded very slowly as contrasted with former periods. On the 11th of June the water broke in and continued to trouble the works for six weeks. Having succeeded in repelling this attack, the progress for the whole year amounted to 117 feet. Foreseeing that he should at some future period, have to account for the causes of these delays, Sir Isambard instituted, in the course of the year (1836), distinct sets of records for every branch of the service, afloat as well as underground, in order to place beyond doubt, the circumstances which might not otherwise be credited. These registers enabled him to give the minutest details of the work, and would, he hoped, be found useful in any future similar undertaking. Through the whole of the year 1837, the progress was only 28 feet 4 inches, a rate which hardly exceeded that of a fortnight of the year 1827. Two irruptions took place within the range of eight feet, owing to the looseness of some portions of the strata, which were so fluid, that the only expedient for advancing, was by forcing forward some of the polings with the screws. The frequent bursts of gas at that period, and in 1838 and 1839, had moreover such an effect upon the men, that some of them fell senseless at their post. There was therefore great risk of the poling boards falling down, as had been the case before, and causing a total disruption of the ground. In this dilemma, the expedient of connecting the poling boards with each other by hooks was resorted to, forming by this means a complete panel in the face of each of the 36 cells of the shield; the top poling being suspended to the head of the cell, the panel could not be disturbed even with a cavity in front of it; there was likewise an additional means of supporting the polings, by iron spurs resting upon the floor-plates and going into the ground. Notwithstanding the apparent increase of labour occasioned by this addition to the poling-boards, good progress was made, amounting to 249 feet in the course of twelve months, and the hooking was found so safe in its service and its results, that were another tunnel to be constructed, Sir Isambard stated, that he would make the system of attaching the poling-boards, an essential part of the organisation of the shield, being convinced that it might by this means, be worked through the worst ground, with a certainty of safety and success.

February 14.—The President in the Chair.

"*Description of Mr. Clay's new Process for making Wrought Iron direct from the Ore; as practised at the Shirva Works, Kirkintillock, Scotland.*" By William Neale Clay.

In this communication, the author first describes the various stages through which the metal passes, between the reduction of the ore and its arriving at the state of malleable iron, by the ordinary mode of manufacture; and then he explains the process which he has invented, and introduced practically at the Shirva Works.

By the ordinary system of iron-making, the ores are reduced into the state of carburet of iron, and then, by refining and puddling, the metal is de-carburetted, thus making it into malleable iron by a number of processes, which are recapitulated:—

1st. Calcining the ore.

2nd. Smelting in a furnace, by the aid of blast, either cold or heated, with raw coal, or coke, for fuel, and limestone as a flux.

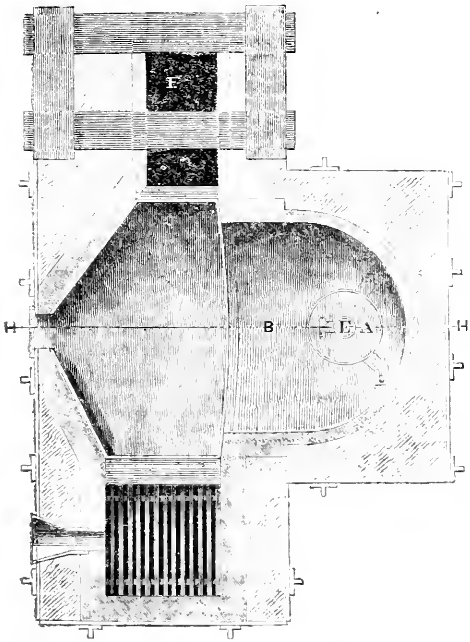
3rd. Refining the "pig" into "plate" iron.

4th. Puddling, shingling, and rolling, to produce the "rough," "puddled," or No. 1 bars.

5th. Cutting up, piling, and rolling, to produce "merchant," or No. 2 bars.

6th. A repetition of the same process, to make "best," or No. 3 bars.

Seeking to diminish the number of manipulations, by the new process a mixture of dry Ulverstone, or other rich iron-ore (Hæmatite) is ground with about four-tenths of its weight of small coal, so as to pass through a screen of one-eight of an inch mesh. This mixture is placed in a hopper, fixed over a preparatory bed, or oven, attached to a puddling furnace of the ordinary form. While one charge is being worked and balled, another gradually falls from the hopper, through the crown, upon the preparatory bed, and becomes thoroughly and uniformly heated; the carburetted hydrogen and carbon of the coal, combining with the oxygen of the ore, advances the decomposition of the mineral, while by the combustion of these gases, the puddling furnace is prevented from being injuriously cooled. One charge being withdrawn, another is brought forward, and in about an hour and a-half the iron is balled, and ready for shingling and rolling. The cinder produced, is superior in quality to that which results from the common system; it contains from 50 to 55 per cent. of iron, and is free from phosphoric acid, which frequently exists, and is so injurious, in all the ordinary slags: when re-smelted, it produces as much No. 1 and No. 2 cast-iron, and of as good quality, as the ordinary "black band" ore of Scotland. The cast-iron produced from the slag (amounting to one-third of what was originally contained in the ore) is mixed with the ore and coal in the puddling furnace; and thus, while nearly all the iron is extracted from the ore, as much wrought iron is produced in a given time, and at the same cost of fuel, as by the old system. The first process, producing puddled bars of superior quality, is consequently on a par with the fourth stage of the old system, as it avoids the necessity of the preceding separate manipulations. From the absence of all deleterious mixture, by once piling and reheating the rough



Scale ¼ inch to a foot.

bars, iron is produced, of a quality in every respect equal, and in powers of tension superior, to that which results from the second piling and reheating in the common mode; it is therefore contended that the two processes produce from the hæmatite nearly one-third more iron, of as good a quality as is usually obtained by the six processes of the old system. The iron thus produced bears a high polish, is very uniform in its texture, is ductile and fibrous, having more than an average amount of tensile strength, and at the same time appears to be more dense, as it possesses a peculiar sonorousness, resembling that of a bar of steel when struck. It has also been converted into steel of a good quality.

The paper is illustrated by a drawing of the furnace necessary for the process, and by specimens of the iron and steel produced.

Remarks.—Mr. Clay contended that the ordinary method of making iron was neither so scientific, nor so practically good as there was reason to expect it would have been, when iron formed so considerable an item in the productive industry of the country. His invention was in some degree based upon the old Catalan fire, wherein malleable iron was produced direct from the ore, although by a considerable expenditure of fuel: by his process the ore was also reduced at one operation into the state of malleable iron, by combination with a large portion of carbonaceous matter; and as the deoxydation of the ore could proceed simultaneously in an adjoining preparatory bed, through which the flame of the puddling furnace traversed, there was necessarily a great saving of time, labour, and fuel in the production of the metal, while the quality was at the same time improved. He argued, therefore, that if the system was generally adopted, a large portion of the capital now sunk in the expensive constructions of blast furnaces, blowing engines, &c., would be dispensed with.

Mr. Taylor observed, that the process appeared to be only applicable to the rich qualities of iron ore, which were now used in comparatively small quantities, as a mixture with the clay ironstones of the coal fields, from which iron was generally produced in this country. There existed large quantities of hæmatite in Great Britain, equal in quality to that of Nassau, or of the Hartz mountains, from which so much iron was made, for converting into steel. The mines of Ulverstone alone now produce 50,000 tons annually, and at least 25,000 tons more could be shipped from Cornwall; and if a demand existed, there was scarcely a limit to the quantity that could be raised. He apprehended that the iron made by this process could be converted into good steel: this was very desirable, as it would render this country independent of Sweden and Russia, whence nearly all the steel-iron was now imported.

Mr. Heath had examined Mr. Clay's process of iron-making, and found that the wrought iron produced from a mixture of Scottish pig-iron and hæmatite ore, was of a superior quality, bearing severe tests without injury. The iron made by this method, from India pig-iron and specular iron ore (per-oxyde of iron) from Devonshire, which was identical in quality with the celebrated Elba ore, when converted into cast steel, by a process which he had accidentally discovered, possessed the quality of welding like shear steel, without any of its defects. The method he alluded to, was to combine manganese with the cast steel in the crucible, and when drawn out under the tilt hammer it could be worked and welded to iron, like shear steel: the consequence of this discovery was, that the latter quality of steel was almost abandoned for cutlery, and the former was now generally used, as it did not exhibit the laminated appearance when polished, which shear steel frequently did. The metal was sounder, and fewer wasters were made. All the brown hæmatites contained manganese, and there was little doubt that, by selecting the proper kinds of ore, malleable iron might be made in Great Britain by this process, as good for converting into steel as any of the Swedish iron. There was abundance of specular iron ore on Dartmoor, equal to the Elba ore, and which would (he had little doubt) produce as good iron as that from the Dannemora ore.

Dr. Faraday remarked, that the process invented by Mr. Clay was founded on sound chemical principles. It was desirable to abandon the use of limestone as a flux; it was proved that the purest limestones contained phosphates, which, although advantageous in agricultural processes, were detrimental in iron making.

Mr. Fox had tried some specimens of Mr. Clay's iron, and found them to bear severe tests, as well as the best cable bolt iron made in the ordinary manner.

Mr. Clay explained that Mr. Heath's process was not indispensable for converting into steel the iron made by his method; and also that argillaceous iron ores, after calcination, could be treated in his furnace, like the hæmatite ores, but not so advantageously.

Mr. Taylor said that 25,000 tons of steel were converted annually in this country, and of that quantity not more than 2500 tons were made from the best Swedish iron; for the remainder, inferior qualities of iron, such as Russian iron, marked CCND, from the forges of Monsieur Demidoff, were used. All that iron was made with charcoal, and could only be called inferior when compared with that made from the Dannemora ore. If Mr. Clay's process was successful in treating the hæmatite ores, as had been stated, it was of great importance, as it would emancipate the country from a dependence upon foreign products. He had recently seen in Germany, a process of producing steel by stopping the operation of puddling pig-iron at a certain point, or intermediate state between cast and wrought iron, and hammering the mass at once into bars. The operation was one of much delicacy, and depended entirely upon the skill of the workman.

Mr. Heath believed the manufacture of steel was involved in unnecessary mystery; it was the general opinion that foreign iron was essential to produce good qualities. Iron as now made from coke furnaces certainly contained too much foreign matter to be used for steel, and it would require more attention to the selection of the materials, before pure iron could be obtained; some of the Low Moor iron, the good quality of which was universally admitted, had been made into blistered steel, but although the springs made with it appeared perfect, it was said that they did not answer so well as those made with steel from charcoal iron. The Sheffield manufacturers required that steel should possess "nature and body;" the first quality to enable it to be rolled and drawn out without cracking, and the second that it might receive and retain a fine edge. Steel made from Garnderris iron (South Wales) possessed "nature," but if made into cast-steel it fled into pieces in working, as it did not possess "body." Steel from German ores appeared to have "body," but wanted "nature." Steel from

Indian iron, although difficult to work, stood better than other kinds when once reduced into form; this he attributed to the purity of the magnetic ore from which it was produced; there was not the slightest trace of phosphorus, arsenic, or any deleterious foreign matter. He was convinced that, with a mixture of Indian pig-iron (which could be produced very cheaply) and Devonshire ore, by Mr. Clay's process, iron could be made of excellent quality for converting into steel at such a reduced price as would render the introduction of Swedish and other foreign iron unnecessary.

Mr. Taylor believed that improvement in the quality of steel, rather than reduction in the price, was the object to be sought. In the large quantity used in the mines under his direction, the dearest steel was found to be the more economical. He had seen as many as 12 dozen borers used to make one blast hole, and unless the tools kept their points well, the labour of the men was thrown away.

February 21.—The President in the Chair.

Mr. Giles presented a plan and sections of London Old Bridge, made from his surveys of it in 1820, *by order of the Committee of the Bridge Lands, with descriptive notes.*

The plan represents the stirlings, piers, parapets, and roadway of the old London Bridge, its low-water channels, called locks, with the soundings through the locks. The sections represent an elevation and levels of the stirlings, piers, arches, roadway, and locks, with levels of the tides observed at the bridge in September and October, 1820; the datum to these levels being the Trinity high-water mark of London, which is recorded on a stone let into the lower external wing of the Hermitage entrance of the London Docks.[1]

From the plan it appears that—

	Ft.	In.
The aggregate waterway between the piers above sterling height was	524	2
The width occupied by the piers	406	10
Making the total length between the abutments of the bridge .	931	0
The aggregate waterway below the stirlings at low-water was .	230	11
And the aggregate distance occupied by the piers and sterlings at low-water was	700	1
	931	0

The level of the tides shows—

	Ft.	In.	
The extraordinary high-water mark of springs to be	2	0	above datum.
The average high-water mark of springs between 23rd September and 25th October, below bridge	0	6½	under ditto.
The same above bridge	1	2	,,
Making the high-water of spring-tides above bridge 7½ inches under the same high-water below bridge, owing to the obstruction which the piers presented to the tides attaining their full height above bridge: and this difference was found commonly to be 8 inches.			
The average high-water mark of neap-tides above bridge was	4	3	,,
And the difference of high-water of neap-tides below and above bridge was not observable.			
The average level of low-water mark above bridge was	14	5	,,
The average level of neap-tides low-water mark below bridge was	16	6	,,
The average level of spring-tides low-water mark was	18	9	,,

Thus the average fall of water through the locks of the bridge at neap-tides was 2 feet 1 inch, and the same at spring-tides was 4 feet 4 inches. But an extreme fall of 5 feet 7 inches was observed through these locks on the occurrence of a high land flood, and a spring-tide ebb.

Having completed the surveys of old London Bridge, Mr. Giles subsequently took the levels of the tides from thence to Teddington lock, and found that in the absence of high winds and land floods, the high-water of spring-tide on the upper side of London bridge attained its level or height at all the London bridges, also at Battersea, Putney, Kew, and Richmond bridges, and at Teddington lock.

"*Account of a series of experiments on the comparative strength of solid and hollow Axles.*" By John Oliver York, Assoc. Inst. C. E.

The author first describes the causes of fracture in railway axles, which he attributes to the sudden strains and injury produced by concussion and vibration. Those resulting from concussion are chiefly ascribed to a defective state of the permanent way, any sudden obstacle opposing itself to the progress of the train, and the severe shocks arising from the wheels coming in contact with the blocks and sleepers when thrown off the line. The force of vibration and its certain effect to produce fracture in a body so rigid as a railway axle, is then fully explained; the evil arises from the impossibility of diverting from the axle the continued series of slight blows or vibrations to which it is subject, or of causing a free circulation of them through its entire length, since the naves of the wheels being fixed tightly on to the axles, form a point on either side for the vibrations to cease, and the particles of iron composing the axle at this point become dislocated by the continued and unequal strain, and ultimately break; the same action is described as taking place in the journal of the axle, and hence the fact that an axle seldom breaks excepting at the journal, or at the back of the nave of the wheel. The twisting strain to which railway axles are subject is next considered, and a calculation entered into, to prove that upon a circle of only a few feet in diameter and assuming a first-class carriage on four wheels to weigh six tons, the strain resulting from this cause is so slight as to be unworthy of consideration in the inquiry. The paper next proceeds to point out, how and why the hollow axle is better able to resist the strains before referred to, than the solid ones now in use.

First, by the process of manufacture, by which the crystallization of the iron is avoided, and it is left in a better state for sustaining sudden strains and continued action. Secondly, by the position of the metal composing the axle, since the comparative strength of axles are as the cubes of their diameters, and their comparative weights only as their squares, consequently, with less weight there must be increased strength; and thirdly, that the vibration has a free circulation through the length of the axle, no part being subject to an unequal shock from the vibration, and the axle would therefore receive much less injury from this cause. In conclusion, it is submitted that a railway axle should possess the greatest possible degree of rigidity between the wheels, to prevent it from bending or breaking from concussion, combined with the greatest amount of elasticity and freedom in the particles of iron within the axle itself, to prevent the injurious effects of vibration.

The details of a numerous set of experiments are then given, to prove the superiority of the hollow axle in all these respects, the average of the whole of which is thus stated. As regards rigidity to sustain a dead weight. The axles being supported at the ends, and the weights applied in the middle.

The paper is illustrated by specimens of the broken axles, both hollow and solid, and by diagrams of the mode of manufacturing the two kinds of axles.

Remarks.—Mr. Geach presented a series of specimens of ends broken off solid axles, made by the Patent Shaft and Axle Company, Wednesbury; they have borne severally 886, 148, 293, and 278 blows of a sledge hammer, weighing 38 lb. before they separated from the body · above twenty more ends had been broken off, the weakest requiring 138 blows. The diameter of these journals was 2¼ inches. An axle was exhibited which had been bent nearly double under an hydraulic press, with a pressure of 65

[1] Low-water mark is 17 feet 10 inches below the lower edge of this stone, settled by the Corporation of Trinity House, August 1800, (39 and 40 Geo. III., cap. 17, sec. 55.)

tons: the journals ($2\frac{1}{2}$ inches diameter) were also bent in opposite directions, by repeated blows of the sledge-hammer, without any signs of fracture being perceptible. The firm, which Mr. Geach represented, had made upwards of 2500 axles, and had tried a very large number by breaking them: they almost uniformly found them of good quality, which might be attributed to the mode of manufacture. Around a centre bar of iron were placed eight bars rolled to a proper form to complete a circle; they were then welded together by rolling, and finished under the hammer; the fibre of the iron, it was contended, was thus worked, and remained in its most favourable position. He was not opposed to the principle of hollow axles, but he wished to prevent any unnecessary prejudice against solid ones by inferences from any one set of experiments; he would therefore suggest that another series of experiments should be made between the relative strength of the two kinds of axles, for which he would contribute the necessary number of solid ones.

Mr. York described the manner in which the solid axles had been selected for the purpose of experiment. Having obtained General Pasley's consent to be present on the occasion, he ordered axles from the Patent Axle Company, and another eminent maker, and selected also several other axles supplied by the Patent Axle Company to the London and Birmingham Railway; these axles were new, never having been under any carriage; be contended that the result of the experiments afforded a fair specimen of the axles generally in use, and were such as the public were in the habit of riding upon. The axles which had since been made by the Axle Company, and were then exhibited to the meeting, showed a quality of iron which could not be surpassed: if this was the usual quality made use of by that company, it still more forcibly proved his position as to the uncertainty of manufacturing solid axles, for while one specimen took a great number of blows to break it, the majority of them were fractured by a slight force; it was this uncertainty which he proposed to avoid, and he contended that it was inseparable from the method of making axles described by Mr. Geach, for in passing the faggot through the rolls to weld the bars together it frequently happened that they were only united to a depth of one-half or three-quarters of an inch, hence it was to a certain extent hollow, and partially avoided the injurious effect of hammering; if, on the contrary, they were perfectly welded, the iron became crystallized, as in any other solid axle; this fact was proved by the specimens before the meeting, those that were solid having been broken by very little force, and the unsound ones requiring a great number of blows to produce fracture. In the experiments, the hollow axles had broken under a different number of blows, but this was owing to their having been made of larger diameter in the journals than the solid ones (but with only an equal quantity of metal in them) and afterwards turned down to the same diameter, which left them of unequal thickness and too thin for a fair test; still, however, with less metal than in the solid ones, they were stronger; this might be accounted for by the mode of manufacture, as by retaining the axle hollow the crystallization of the iron was avoided. The present mode of making the hollow axles he described to be by taking two trough-shaped semicircular pieces of iron, bringing their edges together, and welding them under a hammer between swages. He however dissented from the process of hammering, and intended to finish his hollow axles by compression only. This, he contended, would avoid the injury done to the iron by the present mode of manufacture, and that with the same quantity of iron, the strength of axles being as the cubes of their diameters, and their weights only as the squares, a hollow axle must possess considerable advantage over a solid one. Hollow axles had long been considered desirable, but the expense of making them had hitherto prevented their use; he had reduced their cost by his process to the same rate as the solid ones, and felt confident that in bringing them under the consideration of the profession, through the Institution, they would be fairly treated and ultimately adopted.

General Pasley confirmed the correctness of the results recorded by Mr. York, and the satisfactory nature of the experiments, which had impressed him with a favourable opinion towards hollow axles. It was of importance to avoid deflection, as it was almost as fatal as fracture in causing accidents. After the late accident on the North Midland Railway, he observed a solid axle bent into the form of the letter C, and the upper portions of the periphery of the wheels nearly touching each other. The hollow axles would certainly resist deflection better than solid ones of corresponding weight.

In answer to a question, Mr. York said that the iron was chiefly injured by the amount of hammering which it received in forging.

Mr. Taylor remarked, that the question of the amount of injury received by iron in working, was discussed at the meeting of the British Association in 1842, and the effects of vibration and electricity had also been treated of by foreign engineers. It appeared to be generally admitted, that the great source of mischief was the cold swageing, which the iron received, in order to give the work a good appearance. In order to test this, Mr. Nasmyth subjected two pieces of cable bolt iron to 160 blows between swages and afterwards annealed one of the pieces for a few hours. The unannealed piece broke with five or six blows of a hammer, showing a crystallized fracture; while the annealed piece was bent double under a great number of blows, and exhibited a fine fibrous texture. The fact of the fibre being restored by annealing was well understood and practised by smiths, particularly in chain-making.

Mr. York could not entirely subscribe to the great benefit of annealing, as he had found that after annealing one end of a hollow axle for 48 hours, it was broken off by 82 blows, while the other (unannealed) end of the same axle resisted as far as 78 blows.

In answer to a question from Alderman Thompson, Mr. York said that he had found as much mischief arise from over-heating iron as from over-hammering it; but the difference of the appearance of the fracture, indicated immediately when iron had been burned.

Mr. Taylor said that in Mr. Nasmyth's experiments, the over-heated iron was almost as fragile as glass.

Mr. Gravatt believed that vibration, whether caused by the smith in working the iron, or by the use to which the bar was appropriated, was the reason of its fracture, and it was certain that a constant change was going on in all manufactured iron. At the Thames Tunnel the "fleeting bars" used as levers for turning the large screws for forcing forward the shield, never lasted longer than three or four weeks, although they were very strong, and were made from the best materials by careful smiths. They were only used occasionally, and then without any concussion, having only the power of eight men exerted upon them: yet they broke constantly, and the fracture exhibited a bright crystallized appearance. It was found at last, that in order to give them duration they should be left rough, and not hammered much in working.

Mr. Newton observed that full 10 years since, Dr. Church had used hollow axles for his experimental steam coach on common roads, being convinced of their superiority.

Mr. Fox was an advocate for the hollow axles, but he did not consider the present experiments quite conclusive, as there were differences in the relative dimensions of the axles experimented upon; he would suggest another series of trials, upon a larger number of axles, as the subject was one of great importance, not only to manufacturers but to the public, whose safety in travelling depended upon the goodness of the axles under the carriages. He had used upwards of 5000 axles made by the Patent Axle Company, and had made many experiments by breaking them; the average result was equal to that quoted by Mr. York. He agreed in the danger arising from over-heating iron, as also from over-hammering it, and for some time past he had caused all the axles to be made six inches longer than was necessary, in order to cut three inches off each end, to try the quality and the appearance of the fracture of the iron.

The President remarked, that there could not exist a doubt as to the greater strength of a hollow axle, as compared with a solid one, both containing the same weight of material; the principal question to be considered was, that of vibration, and its effect upon the cohesive strength of the metal; whether the action upon the particles was more irregular in the solid body and more distributed in the hollow one; he recommended this investigation to some of the mathematicians who were present; the result of their inquiries might materially aid in the development of truth from the practical experiments.

February 28.—The PRESIDENT in the Chair.

"*Description of the Roofs over Buckingham Palace, covered with Lord Stanhope's composition.*" By Peter Hogg, Assoc. Inst. C. E.

The mixture invented by Lord Stanhope, and used by the late Mr. Nash, for covering the nearly flat fire-proof roofs of Buckingham Palace, is described in the paper as being composed of Stockholm tar, dried chalk in powder, and sifted sand, in the proportions of three gallons of tar, to two bushels of chalk, and one bushel of sand, the whole being well boiled and mixed together in an iron pot. It is laid on in a fluid state, in two separate coats, each about three-eighths of an inch in thickness, squared slates being imbedded in the upper coat, allowing the mixture to flush up between the joints the whole thickness of the two coats, and the slates being about an inch. The object in embedding the slates in the composition, is to prevent its becoming softened by the heat of the sun, and sliding down to the lower part of the roof, an inclination being given of only $1\frac{1}{2}$ inch in 10 feet, which is sufficient to carry off the water, when the work is carefully executed. One gutter, or water-course, is made as near to the centre as possible, in order to prevent any tendency to shrink from the walls, and also that the repairs, when required, may be more readily effected. It is stated, that after a fall of snow it is not necessary to throw it from the roof, but merely to open a channel along the water-course, and that no overflowing has ever occurred; whereas, with metal roofs it is necessary to throw off the whole of the snow on the first indication of a thaw. These roofs have been found to prevent the spreading of fires, and it is stated, that on one occasion, to test their uninflammability, Mr. Nash had a bonfire of tar barrels lighted on the roof of Cowes castle. Another advantage is stated to be, the facility of repair which the composition offers, as if a leak occurs, it can be seared and rendered perfectly water-tight, by passing a hot iron over it; and when taken up, the mixture can be remelted and used again. The author proposes to obviate the disadvantage of the present weight of these roofs, by building single brick walls at given distances, to carry slates, upon which the composition should be laid; instead of filling the spandrils of the arches with solid materials, as has been hitherto the custom.

The reported failures of this species of covering at Mr. Nash's house in Regent Street, and in other places, are accounted for by the composition having been used in one thin coat, laid upon an improper foundation of laths and tiles. The durability of the roofs, which were carefully constructed day (16th May last) brought into operation for nearly 20 miles on the Great Western Railway.

It is no slight proof of the energy with which Mr. Cooke followed up his great object, in contradistinction to the proceedings of others who had been experimenting with the subject for many years, that within three weeks of his first conceiving the idea, he had constructed at Frankfort two galvanometer telegraphs, capable of giving 26 signals; he had also invented the detector, by which injuries to the wires, whether from water, fracture, or contact, were readily traced, an instrument which Mr. Cooke still retains in constant use; and without which, indeed, an electric telegraph would be impracticable: he had also invented the alarum, on the same principle as one of those in use at the present day.

But the leading feature of the invention at this early period, and which still most strongly distinguishes it from that of Messrs. Cooke and Wheatstone's telegraphs, and all others since exhibited in this country, consists in this, that the telegraph did not merely send signals from one place to another, but included a reciprocal system, by which a mutual communication could be practically and conveniently carried on between two distant places; the requisite connexions and disconnexions being formed by pressing the fingers upon keys similar in their action, and the signals being exhibited to the persons sending as well as to the person receiving the communication. This was and still is effected, by placing a system of keys permanently at each extreme end of the circuit of wires, and by providing a draw-bridge by which the circuit is completed for the electricity to pass when signals are received, but which is withdrawn when the signals are to be sent.

This united and reciprocal property is the basis of the electric telegraph, and inseparable from the practical system, and must be borne in mind when the operation of these instruments is explained. Mr. Cooke has since extended this instrument to any number of intermediate instruments included in the same circuit—as on the Blackwall line, where there are two sets, of five telegraphs each, working together—and also to the portable telegraph to be carried by the trains, and temporarily introduced into the permanent line of communication when required.

By Mr. Cooke's telegraph, eight simple signals can be given, and a sufficient number of compound ones, to admit of the 26 letters of the alphabet being used; in addition to which, by further conventional signs, those letters are made to represent figures, and by a mixture of both systems, as was shown, a mixed sentence, consisting of passages from a code, spelling and figures, could be telegraphed together.

Mr. Cooke first adopted the plan of laying the telegraph wires in iron tubing on the Great Western Railway, and afterwards laid down a double line on the Blackwall Railway, and others on the Leeds and Manchester, and Edinburgh and Glasgow Railways. This plan, though perfectly successful, was extremely costly and difficult to repair when injured, though by aid of an instrument, the detector, less difficulty than could be supposed offered itself to the detection of the injured part, though buried and out of sight. More recently, Mr. Cooke invented, after extensive experiments at his own residence, and carried out on the Great Western Railway, a plan of suspending the conducting wires in the open air from lofty poles. Its leading advantages are—1st. Diminished cost; 2nd. Superior insulation; 3rd. Facility of repair. The old plan consisted of laying copper wires, covered with cotton, and carefully varnished into smooth iron tubing—with frequent arrangements for obtaining access to the wires, and for the facility of examination and repairs. The tube, after being carefully tarred, was either buried in the ground or fixed on low posts, and covered with a wooden rail. This plan will still be occasionally applied in conjunction with the new one, in tunnels, towns, &c.

The cost of the original plan stands nearly as follows.

	£	s.	d.
Prepared ¾ tube, varnished within and without, 5½d. per foot	115	10	0
Six copper wires, covered and varnished, at £6. 15s. per mile	40	10	0
Labour and carriage, per mile	27	0	0
Iron fittings, boxes, &c.	12	6	0
Tar, pitch, paint, rosin, and sundries	15	0	0
Posts and rails, at 3½d. per foot, including fixing	77	0	0
The total cost of the original plan per mile	£287	6	0

To which a per centage for casualties, profit to the contractor, and the price of instruments remains to be added.

The cost by the present plan of suspension may be estimated thus.

	£	s.	d.
Drawing posts, with winding apparatus, per mile	48	0	0
Cast-iron standards, with insulators, (22 in a mile)	52	0	0
Labour in fixing and painting	12	6	0
Anti-corrosion paint and tar	11	0	0
Carriage, tools, and sundries	13	0	0
Contingencies	13	0	0
	£149	6	0

Making a reduction of about 50 per cent. in favour of the present plan—and a still greater advantage in favour of the permanency of the work.

The present method of proceeding in laying down the telegraph, is first, to fix firmly in the ground, at every 500 or 600 yards, strong posts of timber from 16 to 18 feet in height, by 8 inches square at bottom, and tapering off to 6 by 7 inches at top, fixed into stout sills and properly strutted. Attached to the heads of these posts are a number of winders for stretching the wires, corresponding with the number of conducting wires to be employed; and between every two of such posts, upright wooden standards are fixed about 60 or 70 yards apart. A ring of iron wire, (No. 7 or 8,) which has been formed by welding the short lengths in which it is made together, is then placed upon a reel carried on a hand barrow, and one end being attached to the winder at one draw-post, the wire is extended to the adjoining draw-post, and fixed to its corresponding winder at that post; by turning the pin of the ratchet wheel with a proper key, the wire is tightened to the necessary degree, thus the greatest accuracy may be attained in drawing the wires up till they hang perfectly parallel with each other. To sufficiently insulate the wires so suspended at the point of contact with the posts, is an object of indispensable importance, as the dampness of the wood during rainy weather would otherwise allow the electric fluid to pass off freely into the earth, or into an adjoining wire, and thus complete the circuit without reaching the distant terminus at which the telegraphic effect is to be produced. To effect this object at the draw-posts, wooden boxes are employed to enclose that portion of the post to which the winders are attached, and small openings are left for the free passage of the wires, without risking any contact with the outer box. The standards are furnished either with covers parted off by an overhanging fillet between each wire, and again between the lowest wire and the earth, or by a series of metal shields. An eye of metal, with a slit on the upper side, forms a hook to support the wire, and to insulate the wire from the hook, which might otherwise act as a conductor to any dampness in the wood, a split quill is slipped over the wire on which it rests. The whole is then carefully painted with several coats of anti-corrosion paint; or asphalte varnish may be employed for the wires. When the wires are to be varnished, they are unhooked from the upper ends of the standards, and lowered to nails temporarily fixed to receive them toward the bottom of the posts. A painter furnished with a can of paint, hung on his shoulder, a brush, and a piece of felt, takes each wire and rapidly coats it, when it is again hooked up in its position at the top of the standard. This is the simplest and cheapest method now adopted. But for long distances Mr. Cooke employs earthenware or glass for his insulation, and cast iron standards and posts with ash tops for drawing and suspending the conductors, which, instead of single wires, will be strands of six or more wires twisted together; for very great distances, when very superior conducting power will be needed, a copper wire will be placed in the centre of the strand, and whilst it adds but little to the weight, it will more than double the conducting power thereof, the iron wire still giving the necessary strength to resist tension. The relative conductive powers of copper and the softest iron wire are nearly as seven to one. Various methods are adopted in passing under bridges, which answer the purpose of draw-posts, the winders being fixed to a piece of wood partly let into the brickwork to avoid damp, the greatest enemy to electric conduction. These earthenware insulations are introduced between the winder and wire. Mr. Cooke also intends to use caps or boxes of earthenware to surmount the iron standards. At Slough, for half a mile in approaching and passing by the station, cast iron standards and draw-posts are employed, the effect of which is remarkably light and elegant; a line of six wires is there completed, and in crossing over a carriage shed immediately opposite to the station, the wires are stretched over a length of 438 feet without any intermediate support, and so accurately are they arranged, that no difference is perceivable in their parallelism: the draw-posts in this instance are half a mile apart, although the line is slightly curved. In passing over a station, or an accommodation road, or in crossing the railway, loftier standards are employed, which abruptly lift the wires to the height of 25 or 30 feet in order to clear objects passing below. In the latter case lighter wires are employed, that the tension out of the direct line of strain may not draw the standard from the perpendicular.

The last advantage which need be noticed in connexion with this very important step in the invention, arises from the very perfect insulation from the earth. This allows of the employment of the earth as half of the conducting circuit, without risk of the current finding a shorter course through some imperfectly insulated point. For nearly two years Mr. Cooke has tried this plan successfully on the Blackway Railway, and since on the Manchester and Leeds Railway; but where, as in these instances, the wires are enclosed in an iron pipe, there is always danger of a contact, either partial, from a few drops of moisture, or perfect, from the metals of the wire and pipe touching, in which case, as before observed, the electricity takes a short course instead of performing its entire circuit, and no signal is given at the distant terminus, though appearing very strong at the point whence it sets out. With the wires suspended in the air no such danger exists, whilst two advantages spring from the employment of the earth as a conductor. 1st, one wire is saved in each circuit, thus diminishing complexity and cost; and 2nd, the earth acting as a great reservoir of electricity, or as some think as an excellent conductor, the resistance offered to the transmission of the electricity is vastly diminished, and the battery is able to work through a much greater distance with a smaller conducting wire. It is thus that the apparatus exhibited can be made to work with two wires only.
